There are several topical retinoids currently available that are derivatives of vitamin A and are effective for the signs of photoaging (see Chapter 41, Psoriasis). Tretinoin (all-trans-retinoic acid) is available as a cream (0.02%, 0.025%, 0.0375%, 0.05%, and 0.1%) or gel (0.01%, 0.025%, 0.04% [in microspheres], 0.08% [in microspheres], 0.1% [in microspheres]) and tazarotene (available as a 0.05 or 0.1% cream, 0.1% foam, and a 0.05% or 0.1% gel) are the only two topical retinoids FDA approved for the treatment of photoaging. These agents are effective in partially reversing some of the clinical and histologic changes of photoaging by lessening fine wrinkles, mottled pigmentation, and the tactile roughness associated with photoaged skin through mechanisms such as inhibition of metalloproteinase expression.[139–142] Additional benefits of retinoid therapy include the formation of new dermal collagen and vessels, reduction in the number and melanization of freckles, resorption of degenerated connective tissue fibers, and treatment of premalignant and malignant skin lesions.[143] In one of the initial trials, all subjects treated (100%) demonstrated global improvement in the signs of photoaging, with 53% showing moderate changes and the remainder having at least slight improvement. Of the clinical parameters assessed, the most impressive improvements were found with facial skin sallowness, with respondents developing a healthy, rosy glow.[140] These agents are more potent than the retinoids found in over-the-counter products such as retinyl esters, retinol, and retinaldehyde and therefore produce more profound results.

CASE 42-5, QUESTION 3: Would P.B. be an appropriate candidate for therapy with a topical retinoid product (e.g., tretinoin)?

Topical retinoid therapy is most effective for patients 50 to 70 years of age with moderate-to-severe photoaging and for prophylactic use in patients undergoing the initial changes of photoaging.[139] Recently, P.B. has noticed some of the skin changes consistent with early photoaging and would be a good candidate for prophylactic therapy with topical tretinoin. Treatment may improve her sallow skin color and lessen the mottling on her face and forearms and fine wrinkles at the corners of her eyes and mouth, as well as prevent worsening of the photoaging process that she is experiencing.

CASE 42-5, QUESTION 4: P.B.'s physician calls you asking for dosing recommendations for tretinoin. What advice do you provide?

Because both the beneficial and adverse effects of topical retinoid therapy are dose dependent, the underlying goal is to provide the maximal benefit by using the highest concentration that causes minimal skin irritation. Considering P.B.'s skin sensitivity to soaps, cosmetics, and perfumes, her skin is likely to be irritated easily by topical therapy; therefore, it would be best to initiate therapy with the lowest strength (e.g., tretinoin 0.025% cream or tazarotene 0.05% cream). These agents are usually applied every night at bedtime, but in some instances, they are applied initially on an every-other-night basis until the skin accommodates to the irritant effects. The likelihood of irritation depends on the type of vehicle more than the concentration of the agent.[143] The cream or the microsphere gel formulations cause the least skin irritation and would be preferred for initiating therapy for P.B. The microsphere gel formulation is preferred for patients with persistent acne or for those with focal actinic lesions. Younger patients often prefer the gel because it leaves no residue and is compatible with most cosmetics. The solution and gel may be better tolerated in older patients with oily, thick, pigmented skin.

CASE 42-5, QUESTION 5: You are now dispensing tretinoin cream 0.025% to P.B. What patient counseling should P.B. be given?

Before applying the cream to her face at bedtime, P.B. should wash her face gently, using her fingertips and mild soap, then pat her skin dry with a towel. If gentle washing with her fingers does not remove the dry, peeling skin, a washcloth can be used gently on the face. The treated stratum corneum is fragile, and erosions could occur if P.B. is not careful when washing. After waiting about 15 minutes, she should apply a pea-sized amount of cream to her forehead and spread the cream evenly over her entire face. Care should be exercised while applying the cream to the areas adjacent to the eyes and mouth because tretinoin can cause irritation and burning of mucous membranes.

Skin irritation can be expected to start in the first 3 to 5 days of therapy and, hopefully, will subside in 1 to 3 months. Irritation can manifest as erythema, peeling, burning, and stinging. If P.B. experiences excessive irritation, she can reinitiate the regimen on a slower timeline by applying the cream on an every-other-night or every-third-night basis for the first 2 weeks to reduce skin irritation, or she can also apply a topical corticosteroid product such as hydrocortisone 1% cream. Once she begins to tolerate the therapy, her frequency of applications and strength of cream should be titrated to cause mild scaling with only occasional mild erythema. A thicker film of cream can be applied to photodamaged areas. After 9 to 12 months of therapy, she can begin maintenance therapy, which consists of application two or three nights a week indefinitely.

Because these agents can dry the skin, P.B. should be counseled to use moisturizers during the day to help decrease the dryness and irritation of the skin. Nighttime application of moisturizers should be discouraged when topical tretinoin is being used because the moisturizers can cause a pH incompatibility with the cream and possibly dilute the concentration of tretinoin. With a thinning of the stratum corneum, P.B.'s skin may be more susceptible to the effects of UVR. For this reason, as well as to prevent further actinic damage, P.B. should begin prophylactic daytime application of a sunscreen. Considering her skin type (III) and early photoaging changes, a sunscreen with an SPF of at least 30 would be appropriate. P.B. should be counseled not to become discouraged by any apparent lack of response; her skin damage is mild, her response to therapy will be gradual, and part of the goal of therapy is to prevent further damage. Her wrinkles may actually appear to worsen early in therapy owing to an initial buildup of the stratum corneum. P.B. should avoid facial saunas and irritating soaps and cosmetics. Retinoids are recognized as being teratogenic, and although risk is more highly associated with oral forms more commonly used for acne, use should generally be avoided in any patients who are pregnant or planning to become pregnant.[144]

BURN INJURIES

Incidence, Prevalence, and Epidemiology

Approximately 486,000 Americans are treated for burns annually.[145] Although admission for and mortality from burn injuries continues to decline, the total number of emergency department visits remains elevated, with over 40,000 individuals requiring hospitalization; burns cause an overall yearly mortality of over 3,200.[146] With the development of multidisciplinary burn centers and a better understanding of the pathophysiology of the burn wound, survival of patients with second- and third-degree burns has improved by 5 to 6 times during the last three decades.[147] Data from the 2015 National Burn Repository Annual Report reviewed the combined data set of acute burn admissions for the time period between 2005 and 2014.[147] Key findings included the following:

- Over 68% of the burn patients were men. The mean age for all cases was 32 years old. Children under the age of 5 years accounted for 19% of the cases, whereas patients age 60 or older represented 13% of the cases.
- The two most commonly reported etiologies were fire/flame and scalds, and accounted for almost 8 out of 10 reported. Scald injuries were most prevalent in children under 5, whereas fire/flame injuries dominated the remaining age categories.
- More than 75% of the reported total burn sizes were less than 10% of total body surface area (TBSA), with a mortality rate of 0.6%. The mortality rate for all cases was 3.2% and 5.7% for fire/flame injuries.
- Seventy-three percent of the burn injuries, with known places of occurrence, were reported to have occurred in the home. Seventy-two percent of cases with known circumstances of injury were identified as accident, nonwork-related.

Burn injuries range from relatively minor, superficial injuries to severe, extensive skin loss resulting from contact with hot solids and liquids, steam, chemical agents, electricity, or other physical agents, such as UVR or infrared radiation. Burn injuries occur in 8 to 12% of all reported abuse cases involving children who come to the attention of healthcare professionals.[148] Teenagers and adults between 17 and 30 years of age most commonly are involved in accidents with flammable liquids, but the mortality associated with clothing ignition continues to decrease as a result of the use of flame-retardant forms of fabric in clothing. Both income and income disparity by country are associated with higher rates of burn-related deaths.[149]

Complications such as fluid and electrolyte imbalances, metabolic derangements, respiratory failure, sepsis, scarring, and functional impairment are the primary causes of hospitalization for these cases. Most burns, however, are minor and can be managed in an ambulatory environment, provided the burned patient is evaluated carefully, the severity of the burn is assessed accurately, and proper and continuous follow-up care is ensured.

The number of serious burns is decreasing in the United States because of better prevention (smoke detectors, water temperature regulations, and decreased smoking), and the advances in acute burn wound management have contributed to this decline as well, including its pharmacotherapy, with topical antimicrobial therapy, early excision or enzymatic debridement of devitalized tissue, and skin grafting or substitutes.[150,151]

Etiology

ZONES OF INJURY

The skin functions as a protective barrier of the underlying organ systems from trauma, temperature variations, harmful penetrations, moisture, humidity, radiation, and invasion by microorganisms (see Fig. 39-1 in Chapter 39, Dermatology and Drug-Induced Skin Disorders). It also is involved with carbohydrate, protein, fat, and vitamin D metabolism, produces secretions that lubricate the skin, is involved with the immune response, and provides the body with the sense of touch.

Burn wounds caused by thermal injury can be described by varying zones of injury.[152] The most peripheral area of injury is the zone of hyperemia. The tissue in this area is characterized by inflammatory changes with minimal tissue damage. The zone of stasis is the next area of injury, extending inward from the zone of hyperemia. This area involves ischemic, damaged tissue, with blood vessels only partially thrombosed. The damaged endothelial linings of blood vessels within this zone of injury may trigger further thrombosis, resulting in further ischemia, cell death, and deepening of the burn wound. This process of further injury can occur 24 to 48 hours after the initial injury. Drying of the burn wound or infection can cause deepening of the burn wound by preventing re-establishment of circulation to injured tissue. The central-most area, or the zone of coagulation, is characterized by thrombotic vessels and necrotic tissue. This area absorbs the most thermal energy, resulting in the greatest tissue damage. Minor burns may involve only the most peripheral zones of injury, whereas severe burns encompass all three zones of injury.

EXTENT OF INJURY

Rule of Nines

Total body surface area (TBSA) is used to assess the size of burns of the skin. The burned surface area is calculated as a percentage of TBSA to determine burn size. In adults, the rule of nines is used to approximate the percentage of burned surface area. Burn severity is proportional to the percent of TBSA involvement and depth of the wound. The percent of TBSA for adults can be estimated by using the “rule of nines,” in which each arm constitutes 9% of the TBSA, the head 9%, each leg 18%, the front and back of the torso 18% each, and the genitalia 1%.[153] For children younger than 10 years of age, the percent TBSA must be adjusted because their bodies have different proportions. Variations of the Lund and Browder chart have been used for this purpose.[154] At birth, the infant’s head constitutes about 19% of the TBSA. For each additional year of age, the head decreases by about 1%, and the BSA of the legs increases by about 1% of the patient’s TBSA, so a quick estimation of the size of a burn can be made.

Classification of Wounds

Burn wounds also are classified according to the depth of tissue damage. Determining the depth of the burn wound can be difficult during the first 24 to 48 hours because of the presence of edema and continued tissue ischemia and infection, both of which can cause deepening of the wound. In addition, the depth of destruction can vary within the same burn, and skin surface characteristics may not match underlying tissue damage, making assessment of the burn wound difficult.[152]

First-Degree Burns (Superficial-Thickness Burn)

First-degree burns result from injury to the superficial cells of the epidermis; a common example is a mild sunburn. The burned skin does not form blisters, but it does become erythematous and mildly painful. This superficial-thickness burn heals within 3 to 4 days without scarring.

Second-Degree Burns (Partial-Thickness to Superficial Burn)

Second-degree burns may be superficial or deep, depending on the depth of dermal involvement. Superficial second-degree burns involve the epidermis and the upper layer of the dermis. The burn surface often is erythematous, blistered, weeping, painful, and very sensitive to stimuli. The erythema blanches with pressure, and the hair follicles, sweat, and sebaceous glands are spared. Superficial second-degree burns heal spontaneously within 3 weeks with little, if any, scarring. Deep second-degree burns involve the deeper elements of the dermis and may be difficult to distinguish from third-degree burns. The burn surface is pale, feels indurated or boggy, and does not blanch with pressure. This wound is less painful than more superficial wounds; some areas may be insensitive to stimuli. Healing occurs slowly over the course of about 35 days with eschar formation and possible severe scarring and permanent loss of hair follicles and sweat and sebaceous glands.

Third-Degree Burns (Partial-Thickness to Deep Burn)

Third-degree burns entail complete destruction of the full thickness of the skin, including all skin elements. The wound may appear pearly white, gray, or brown and is dry and inelastic. Pain is sensed only when deep pressure is applied. If the wound is small, healing over the course of several months can occur by epithelial migration from the margins of the injury, with scar and contracture formation. Third-degree burns are repaired by excision and grafting, or excision and primary closure to prevent contractures of the skin.[155]

Fourth-Degree Burns (Full-Thickness Burn)

Fourth-degree burns are similar to third-degree burns except that devitalized tissue extends into the subcutaneous tissue, fascia, and bone. These burns are blackened in appearance; they are dry and generally painless because of destruction of nerve endings and are at great risk for infection.

COMPLICATIONS OF SEVERE BURN WOUNDS

Fluid Loss

In severe burns, release of vasoactive mediators and capillary injury cause sequestration of large amounts of body fluid, plasma, and electrolytes in extravascular compartments, resulting in edema both locally and throughout the entire body. This redistribution of fluid is compounded by the loss of large amounts of fluid, electrolytes, and protein into the open wound. The cumulative effect is a marked decrease in blood volume, a fall in cardiac output, and decreased tissue and organ perfusion. During the first 24 to 48 hours after a severe burn injury, adequate fluid must be given to replace fluid lost from the vascular space to prevent shock and, possibly, multiple-organ failure and death.[156]

Infection

The most important threat to survival of the fully resuscitated patient is infection, with burn wound sepsis and pneumonia being the leading causes of death.[156] The local mechanical defenses of the skin and respiratory tract often are damaged in burn victims, making these common foci for fatal infections. Loss of circulation to the burn wound margins does not allow proper functioning of cellular and humoral defense mechanisms, which increases susceptibility to infection. Devitalized tissue and tissue exudates provide an ideal environment for the proliferation of bacteria. Colonization of gram-positive bacteria occurs if topical antimicrobial therapy is not initiated promptly, and gram-negative bacteria may predominate by the fifth day after injury.[156] Systemic antibiotics are of limited benefit in full-thickness burns and are used only to treat infections documented by wound biopsy, which reveal in excess of 10^5 bacteria per gram of burn tissue.[157] Topical antimicrobials, local wound care, and strict infection control practices are the mainstays of controlling burn wound infections. Devitalized tissue initiates and perpetuates a sepsis-like state in the absence of an identifiable focus of infection.[156] For this reason, as well as for infection control, early excision of devitalized tissue and closure of the burn wound by skin grafting or substitutes have been adopted by many burn centers.

Inhalation Injury

Burn injuries complicated by inhalation injury are associated with greatly increased mortality rates. Injury to the tracheobronchial mucosa is caused by inhalation of smoke or flames and may result in bronchospasm, ulceration of the mucous membranes, damage to cell membranes, edema, and impairment of bacterial ciliary clearance. Even patients with minor burns can have inhalation injury and require hospital admission. The early symptoms of pulmonary injury (hoarseness, dyspnea, tachypnea, and wheezing) may not be evident for 24 to 48 hours, so patients with suspected inhalation injury (i.e., facial burns or entrapment in a closed space) must be examined carefully. Singed nasal hair, a soot-coated tongue or oropharynx, and upper airway edema are indications of inhalation injury. The diagnosis is established by bronchoscopy, and management may include endotracheal intubation and mechanical ventilation. Maintenance of the patient’s fluid status is essential. Corticosteroids do not influence survival rates and should not be routinely administered to patients with inhalation injury. They can also increase morbidity and mortality associated with burns and inhalation injury by increasing the risk of infection.[156]

Clinical Management of Minor Burns

TRIAGE

CASE 42-6

QUESTION 1: S.T., a 17-year-old, nonobese boy, has just burned the calf of his right leg on the muffler of his motorcycle. Immediately after being burned, S.T. was able to rinse his leg with cool water from a garden hose. The burn on his leg is about twice the size of the palm of his hand and appears erythematous and weeping. He sustained no other injury, but now he is in considerable pain. S.T. has no significant medical history. Should S.T. be referred to a healthcare provider or can he safely self-treat his burn? What patient information is necessary to consider in making this decision?

Before recommending treatment for a patient with a minor burn, it is important to accurately assess the patient to determine whether he or she can self-treat safely or whether referral or hospitalization is necessary. The location and severity of the burn, the patient's age and state of health, and the cause of the burn injury all must be considered.

American Burn Association Treatment Categories

Three treatment categories for burn injuries are recommended by the American Burn Association: major burn injuries; moderate, uncomplicated burn injuries; and minor burn injuries.[158]

- Major burn injuries are second-degree burns with greater than 25% TBSA involvement in adults (20% in children); all third-degree burns with 10% TBSA involvement; all burns involving the hands, face, eyes, ears, feet, and perineum that may result in functional or cosmetic impairment; high-voltage electrical injury; and burns complicated by inhalation injury, major trauma, or poor-risk patients (elderly patients and those with debilitating disease).
- Moderate, uncomplicated burns are second-degree burns with 15% to 25% TBSA involvement in adults (10%–20% in children); third-degree burns with 2% to 10% TBSA involvement; and burns not involving risk to areas of specialized function, such as the eyes, ears, face, hands, feet, or perineum.
- Minor burn injuries include second-degree burns with less than 15% TBSA involvement in adults (10% in children), third-degree burns with less than 2% TBSA, and burns not involving functional or cosmetic risk to areas of specialized function.

Patients with minor burn injuries may be treated on an outpatient basis if no other trauma is present; if circumferential burns of the neck, trunk, arms, or legs are not present; and if the patient is able to comply with therapy. After initial evaluation by a healthcare provider, patients may self-treat a second- or third-degree burn only if less than 1% BSA is involved.

Major or moderate, uncomplicated burns necessitate hospital admission, and surgical referral is recommended for patients of all ages who have deep second- or third-degree burns covering 3% of the TBSA.

Both the American Burn Association and the American College of Surgeons recommend transfer to a burn center for all acutely burned patients who meet any of the following criteria[159]:

- Partial-thickness burns of at least 20% TBSA in patients aged 10 to 50 years
- Partial-thickness burns of at least 10% TBSA in children younger than 10 or adults older than 50 years
- Full-thickness burns of at least 5% TBSA in patients of any age
- Patients with partial- or full-thickness burns of the hands, feet, face, eyes, ears, perineum, or major joints
- Patients with high-voltage electrical injuries, including lightning injuries
- Patients with significant burns from caustic chemicals
- Patients with burns complicated by multiple trauma in which the burn injury poses the greatest risk of morbidity or mortality (in such cases, if the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center)
- Patients with burns who suffer an inhalation injury
- Patients with significant ongoing medical disorders that could complicate management, prolong recovery, or affect mortality
- Patients who were taken to hospitals without qualified personnel or equipment for the care of children
- Burn injury in patients who will require special social, emotional, or long-term rehabilitative support, including cases involving suspected child abuse or substance abuse

Age- and Disease-Related Recommendations

Children younger than 2 years of age and elderly patients with a burn injury should be referred for evaluation because these patients may not tolerate any trauma associated with the burn. In addition to medical issues, children with burns that result from suspected child abuse should be hospitalized for legal, psychosocial, and protective reasons. Burn patients with any other medical condition, such as diabetes mellitus, cardiovascular disease, immunodeficiency disorders (e.g., human immunodeficiency virus [HIV]-associated disease, patients receiving cancer chemotherapy), renal disease, obesity, or alcoholism, may be more susceptible to complications from the burn and may have compromised wound healing.

ETIOLOGY

The etiology of a burn should always be considered because this may provide some insight into the burn presentation and its management. Electrical burns can appear to be superficial because external injury may occur at only the entrance and exit sites of the current. These burns, however, can cause extensive damage to underlying nerve and muscle tissue that is not initially evident. Except for very minor electrical burns, these patients should be referred for further evaluation. S.T. has sustained a superficial second-degree burn over about 2% of his TBSA. Even though the burn wound on his leg was caused by thermal injury and is relatively minor, S.T. should be referred for further evaluation and treatment.

TREATMENT

CASE 42-6, QUESTION 2: How should S.T.'s burn be treated? What treatment alternatives may be used for S.T.? What immunization should S.T. be questioned about?

Goals of Treatment and Immediate Care

Treatment goals for first- and second-degree burns are to relieve the pain associated with the burn; to prevent desiccation and deepening of the wound and infection; and to provide a protective environment for healing. Immediate care of the wound should be application of cold, wet compresses or immersion in cool water.

S.T. may have prevented extension of the burn to deeper layers of tissue and alleviated some of his pain from the burn by immediately irrigating the wound with cool water. Next, the area should be cleansed with a mild hypoallergenic soap (e.g., Basis, Purpose) and water. The sterile, nonadherent, fine-mesh gauze dressing impregnated with hydrophilic petrolatum (e.g., Xeroflo, Kendall; 3% bismuth tribromophenate) should be placed over the wound. This type of dressing offers bacteriostatic activity and prevents the gauze from adhering to the wound and allows the burn exudate to flow freely through the dressing, thus preventing maceration.

A second layer of absorbent gauze should be placed over the petrolatum gauze, and a supportive layer of rolled gauze can be used to keep the dressing in place. The outer layer must not be too constricting, and the dressing should be replaced every 48 hours after recleaning the area and inspecting for signs of infection. If S.T.'s wound continues to weep, it may be beneficial to soak his wound or apply a towel saturated with water, normal saline, or Burow solution (diluted 1:20 or 1:40) for 15 to 30 minutes at least 4 times daily (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders). The use of butter, grease, or similar home remedies should be avoided in the treatment of burns because these measures tend to retain the thermal energy sustained in the burn and may increase the area of thermal injury. Because burn patients are susceptible to secondary tetanus infections, S.T. should receive a tetanus toxoid booster if he has not been immunized within the previous 10 years.

Skin Substitutes and Synthetic Dressings

Advances in the development of skin substitutes are being used to achieve the elusive goal of finding a skin replacement to mimic completely the interaction and functions of dermis and epidermis. Although this goal has yet to be achieved, a growing number of synthetic and biologic products are available that can serve important roles in caring for burn patients.[159] Examples of some of the current modalities are as follows:

Human Cadaver Skin

Fresh human cadaver skin (allograft) is considered the sine qua non for temporary closure of burn wounds. It adheres well to a healthy wound bed, resulting in reduced contamination and reduced protein, heat, and water loss. With improved stabilization techniques, rejection and disease transmission (e.g., hepatitis) can be delayed for 3 to 5 weeks, and the risk of infection transmission (e.g., hepatitis) is minimized.

Epidermal Substitute: Cultured Epithelial Allografts

Deep injuries (i.e., third-degree or deep dermal burns) lead to dermal damage that impairs the ability of the skin to heal and regenerate on its own. Skin autografting after burn excision is considered the current gold standard of care, but lack of patient's own donor skin or unsuitability of the wound for autografting may require the temporary use of dressings or skin substitutes to promote wound healing, reduce pain, and prevent infection and abnormal scarring. These alternatives include deceased donor skin allograft, xenograft, cultured epithelial cells, and biosynthetic skin substitutes.

Allotransplantation is the transplantation of cells, tissues, or organs, sourced from a genetically nonidentical member of the same species as the recipient. Human deceased donor skin allografts represent a suitable and much used temporizing option for skin cover after burn injury. The main advantages for their use include dermoprotection and promotion of re-epithelialization of the wound and their ability to act as a skin cover until autografting is possible or reharvesting of donor sites becomes available. Disadvantages of its use include the limited abundance and availability of donors, possible transmission of disease, the eventual rejection by the host, and its handling, storing, transporting, and associated costs of provision. The technique of culturing autologous human epidermal cells grown from a single full-thickness skin biopsy into confluent keratinizing sheets suitable for grafting has been available for more than two decades and is especially useful for patients with large wounds.[160] A lack of mechanical stability of cultured epithelium, causing an imperfect cover, remains a major concern; therefore, the development of a dermal substitute (or a vascularized remnant of allogeneic dermis), in combination with cultured epithelial allografts to increase mechanical stability and decrease wound contracture, or a laboratory-derived autologous composite continues to receive scientific investigation.[161]

Animal Substitute: Porcine Skin

Xenografts derived from porcine skin has gained acceptance as a temporary dressing alternative to allograft because of its lower cost and greater availability.[161] At 0°C, frozen porcine skin has a storage life of 6 to 18 months from the date of manufacture. As with an allograft, it has the desirable properties of being able to adhere initially to a clean wound; to cover nerve endings to decrease pain; to function as an autograft test graft; and to diminish heat, protein, and electrolyte loss. Use of porcine xenografts is a cost-effective alternative to allografts in the treatment of burn wounds, especially for partial-thickness skin losses, temporary coverage prior to autograft and to protect meshed autografts. Although porcine skin shares many physical properties with human skin, it is susceptible to hyperacute rejection due to preformed antibodies. A porcine-derived xenograft in a premeshed, de-epithelialized, collagen matrix that can be stored at room temperature (EZ Derm, Mölnlycke Health Care) is thought to be more resistant to bacterial degradation.

Dermal Analogs: Allodermal Grafts

Unlike the epidermis, the dermis can be rendered acellular and still perform its basic protective and supportive functions. With removal of the dermal cells, the antigenic elements are also eliminated; therefore, alloplastic transplantation can occur without rejection. The principle of allodermal grafting is that an ultrathin (0.01 cm) meshed autograft laid on top of the allodermis provides skin quality that is comparable to that obtained from thick partial-thickness skin grafts.

As one example, AlloDerm (LifeCell) is a shelf-stored, freeze-dried, acellular human cadaveric dermal matrix. Integra (Integra LifeSciences) is a porous matrix of cross-linked bovine tendon collagen and glycosaminoglycan and a semi-permeable polysiloxane (silicone) layer. The inner layer of this material is a 2-mm-thick combination of collagen fibers isolated from bovine tissue and the glycosaminoglycan chondroitin-6-sulfate that has a 70- to 200-μm pore size to facilitate host fibrovascular ingrowth. The outer layer is a 0.009-inch polysiloxane polymer with vapor transmission characteristics that simulate normal epithelium. This meshed bilayer allows drainage of wound exudate and provides a flexible adherent covering for the wound surface. The collagen-glycosaminoglycan biodegradable matrix provides a scaffold for cellular invasion and capillary growth.[161]

Semisynthetic or Biosynthetic Dressings

Biobrane (Smith & Nephew), a nylon–collagen mesh, is used commonly for partial-thickness burns.[162,163] It is a bilaminar, semisynthetic, temporary skin substitute made of a silicone film that is bonded to nylon mesh. Once applied to the burn site, blood or sera clot in the nylon matrix to adhere the mesh to the wound until epithelialization occurs. Its adherence is facilitated by collagen peptides bonded to the nylon underlayer. This substitute has been shown to be as effective as frozen human allograft for the temporary coverage of freshly excised full-thickness burn wounds before autografting.[163] Other available biosynthetic dressings are AWBAT (Aubrey) and AWBAT Plus (Aubrey), which contain a silicone–nylon–collagen membrane. Silon TSR (BioMed Sciences) is a synthetic copolymer that serves as a temporary skin replacement, with elasticity, permeability to water vapor and impermeability to bacteria. These agents peel off within approximately 2 weeks as re-epithelialization of the wound bed progresses.[162]

For superficial- to partial-thickness burns, numerous agents are available over-the-counter. Duoderm (ConvaTec) is a hydrocolloid dressing, whereas OpSite (Smith & Nephew) and Tegaderm (3M) are elastomeric polyurethane films. Comfeel (Coloplast) is a semipermeable polyurethane film coated with a flexible, cross-linked adhesive mass containing sodium carboxy-methylcellulose (NaCMC) as the principal absorbent and gel-forming agent. This product is permeable to water vapor, but impermeable to exudates and microorganisms. In the presence of an exudate, NaCMC absorbs fluids and swells to form a cohesive gel that does not disintegrate or leave residues in the wound bed.

Hyaluronic Acid

Produced by fibroblasts, this group of dermal matrices has a demonstrated positive impact on scar-free fetal wound healing and is also used commercially as a dermal filler. It can be obtained from Streptococcus fermentation or extracted from rooster combs. It is available as a scaffold for keratinocytes (Laserskin), an acellular dermal matrix (Hyalomatrix), and as a cellular dermal matrix (Hyalograft-3D).[164]

Alternatives in treating S.T.'s second-degree burn include the use of synthetic dressings and topical antimicrobial agents. Synthetic dressings serve as skin substitutes that are applied to fresh, clean, and moist burns. They are trimmed to about the size of the burn and left in place until the burn is healed or the dressing separates from the wound spontaneously. Indicated for superficial second-degree burns, biosynthetic dressings keep the wound warm and moist, allowing for a faster rate of healing. These dressings offer a significantly lower rate of infection, less frequent dressing changes, with less pain and electrolyte and albumin loss.

Tissue-Engineered Biologic Dressings

Tissue-engineered biologic dressings (examples: Dermagraft, Organogenesis; OASIS Wound Matrix, Smith & Nephew) have been used in the treatment of burns, chronic ulcers, surgical wounds, and other desquamating dermatologic conditions.[165,166] Using an appropriate biologically active matrix to accelerate wound healing and achieving skin reconstruction is well established. Cellular components migrate to the wound from preexisting cell populations in adjacent tissue. Both circulating marrow-derived stem cells and preexisting organ-specific stem cells can contribute to tissue regeneration.[165]

Topical Antimicrobial Agents

Silver Sulfadiazine

Silver sulfadiazine 1% cream (Silvadene, generic; Aquacel Ag [hydrofiber dressing with silver]; ConvaTec) is the usual agent of choice because it has broad-spectrum gram-positive and gram-negative antibacterial activity, provides reasonable eschar penetration, and is easy and painless to apply and wash off. The cream is a 1% suspension of silver sulfadiazine in a water-miscible base. As a consequence of poor water solubility, the active agent shows only limited diffusion into the eschar. Silver sulfadiazine cream is most effective when applied to burn wounds immediately after thermal injury to prevent bacterial colonization of the burn wound surface as a prelude to intraeschar proliferation. This agent has the advantages of being painless when applied to the wound and being free from acid–base and electrolyte disturbances. The limitations of silver sulfadiazine cream include the potential for allergic reactions owing to its sulfadiazine moiety, silver staining of the treated burn wound, hyperosmolality, methemoglobinemia, and hemolysis as a result of a congenital lack of glucose-6-phospate dehydrogenase.[167] Leukopenia, previously considered to be an adverse drug event associated with use of silver sulfadiazine, occurs when using other topical agents during burn care.[167] An evidence-based review of use of silver sulfadiazine in burns suggested that whereas there is evidence of antibacterial activity, no direct evidence is seen of improved healing or reduced infection compared with normal dressings.[168] In partial-thickness burns, use of Aquacel Ag offers less treatment to re-epithelialize burns 100% with less pain, as compared with silver sulfadiazine.[169] This agent should not be applied around the eyes or mouth in patients with hypersensitivity to sulfonamides or in pregnant or breast-feeding women.

Mafenide Acetate

Mafenide acetate (Sulfamylon) is an 11.1% cream formulation of mafenide acetate in a water-dispersible base, or a 5% powder for topical solution. A recent investigation in a pediatric burn population demonstrated the effectiveness of a 2.5% solution, without a change in the incidence of bacteremia or wound infection, and without experiencing adverse drug events.[170] As a water-soluble agent, mafenide diffuses freely to establish an effective antibacterial concentration throughout the eschar and at the interface of viable–nonviable tissue, where bacteria characteristically proliferate before invasion. Because of this characteristic, mafenide is the best agent for use if the patient to be treated has heavily contaminated burn wounds, if treatment is delayed for several days after the burn occurred, or if a dense bacterial population already exists on and within the eschar. Adverse effects include hypersensitivity reactions in 7% of patients (usually responsive to antihistamines), pain or discomfort for 20 to 30 minutes when applied to partial-thickness burns (seldom a cause for discontinuation), and inhibition of carbonic anhydrase. The inhibition of carbonic anhydrase can produce both an early bicarbonate diuresis and an accentuation of postburn hyperventilation. The resulting overall reduction of serum bicarbonate levels renders such patients liable to a rapid shift from an alkalotic to an acidotic state. If acidosis should develop during use of mafenide, the frequency of application should be reduced to once daily, or it should be omitted for 24 to 48 hours, with buffering used as necessary and with efforts made to improve pulmonary function.

Either topical silver sulfadiazine or mafenide should be applied in a one-eighth-inch-thick layer to the entire burn wound with a sterile gloved hand immediately after initial debridement and wound care. Twelve hours later, to ensure continuous topical treatment, a one-eighth-inch coat of cream should be reapplied to those areas of the burn wound from which it has been abraded by clothing. The topical cream should be cleansed gently once each day from all of the burn wound, and the wound should be inspected. Daily debridement should be carried out to a point of bleeding or pain without the use of general anesthesia. After debridement, the wound should be covered again by the topical cream.

In S.T.'s case, silver sulfadiazine cream could be chosen to treat his burn on an outpatient basis if an assessment determines that he is at particular risk for infection. The cream would be applied in a thin layer over the wound and covered with absorbent gauze and wrapped with rolled gauze. The dressing must be changed twice daily to maintain an application of cream that is biologically active. Topical bacitracin and the combination of polymyxin B and bacitracin are transparent formulations that also can be used, but, because of limited efficacy, may be desirable for use only on small, second-degree burns on the face.

Oral Analgesics and Topical Protectants

S.T.'s burn pain can be treated with oral OTC analgesics, aspirin, acetaminophen, or ibuprofen. If these analgesics do not provide adequate relief, oxycodone or acetaminophen (or equivalent) may be of additional benefit.[171] Topical protectants, such as allantoin, calamine, white petrolatum, or zinc oxide, are safe and effective in treating first-degree and minor second-degree burns. These agents protect the burn from mechanical irritation caused by friction and rubbing and prevent drying of the stratum corneum.

Postwound Care

Postwound care is an essential part of total burn management to ensure adequate follow-up subsequent to wound healing, including psychological support. Good burn care that helps to alleviate physical discomfort, pain, and scarring and that promotes good wound healing will also provide psychological benefits for the patient. Healed wounds should be moisturized on a regular basis. Pruritus can be a major problem after burn injury. To reduce itching, moisturizers can be applied, and oral antihistamines may be necessary.[172] Protection from the sun will help to prevent further thermal damage or pigmentation changes to the affected area. Patients in this population should avoid the sun after a burn injury whenever possible, with use of a sunscreen with an SPF of at least 50 recommended.[173] If surface changes occur (e.g., skin becomes hypertrophic, or blisters or new wounds appear), the patient should be advised to return for evaluation.

Osteoarthritis

Dominick P. Trombetta and Christopher M. Herndon

	CORE PRINCIPLES	CHAPTER CASES
1	Osteoarthritis (OA) is a chronic, progressive condition, primarily affecting women, that causes loss of articular cartilage in hands, knees, hips, and cervical and lumbar spine. OA causes significant pain and functional disability, and increases costs to our healthcare systems.	**Case 43-1 (Question 1)**
2	The evolving role of cytokines and the resultant imbalance between cartilage maintenance and destruction contribute to the pathophysiology of OA. There are no current disease-mitigating therapies.	**Case 43-1 (Questions 2, 3), Figure 43-1**
3	The typical presentation includes stiffness and pain unilaterally in one or more joints lasting less than 30 minutes after a period of immobility. This causes significant limitations in activities of daily living as well as overall quality of life.	**Case 43-1 (Questions 1, 2)**
4	Conservative treatment strategies include weight loss, self-management, aerobic exercise, strength training, and physical and occupational therapies to best maintain optimal functional status.	**Case 43-1 (Question 4)**
5	Initial trials of routine dosing of acetaminophen, topical agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and intra-articular glucocorticoid injections represent initial pharmacologic interventions of osteoarthritis.	**Case 43-1 (Questions 5, 6), Case 43-2 (Questions 1–4), Tables 43-1–43-3, Figure 43-2**
6	Intra-articular hyaluronan, tramadol, and duloxetine may be considered in those patients with insufficient relief in symptoms and worsening function after initial pharmacologic strategies have been attempted.	**Case 43-2 (Questions 1–6)**
7	A consistent and systematic approach to the management of chronic pain caused by OA can help identify patients with limitations in activities of daily living (ADLs) and prevent further disability. Then, the effectiveness of current therapies can be more appropriately evaluated, and the treatment plan can be updated.	**Case 43-1 (Questions 5, 7), Case 43-2 (Questions 1–6), Case 43-3 (Questions 1, 2)**

INCIDENCE, PREVALENCE, AND

EPIDEMIOLOGY

Osteoarthritis (OA) is a chronic, progressive disorder characterized by the changes to articular cartilage and bone primarily in hands, knees, hips, and spine. Incidence rates for OA of the hand have been estimated to be 100 per 100,000 person-years, hip OA, 88 per 100,000 person-years, and knee OA, 240 per 100,000 person-years. Incidence rates increase with advancing age until the 8th decade of life. The Centers for Disease Control and Prevention (CDC) reported in 2005 that approximately 26.9 million people older than 65 years of age are affected, particularly after the age of 50.[1] Women seem to be affected by more severe OA of the knees than men, particularly after the age of 50.[2] Additionally, women experience more severe disease radiographically; however, severity of radiologic disease may not predict severity of subjective symptoms of pain or disability. Men have a lower incidence of knee and hip OA than women.[1] More recently, in 2013, it had been reported that arthritis was the most common cause of disability in U.S. adults, and was noted to co-occur in persons with multiple chronic conditions such as heart disease and diabetes mellitus. This report illustrated that 52.5 million (22.7%) of adults older than 18 years had self-reported provider-diagnosed arthritis,

---

and 22.7 million (9.8% of all adults, 43.2 with arthritis) reported arthritis-attributable activity limitations.[3] Arthritis contributes significant costs to the healthcare system through hospitalizations, joint-related surgeries, and inability to work. An estimated 200 billion US dollars is attributed to OA annually as either direct medical costs or lost productivity.[4]

Arthritis patients perceive lower health-related quality of life. The physical limitations in arthritis-related activities and the subsequent effects on the comorbidities related to obesity are current areas of research.[3] Considering the morbidity and mortality associated with type 2 diabetes mellitus and coronary artery disease is significant. The development of disease-mitigating interventions may benefit not only those with OA but also in cases where inactivity contributes to or worsens obesity-related conditions and complications.

ETIOLOGY

Osteoarthritis has been previously described as disease of cartilage that has undergone significant wear and tear. It is now known to be a more complex and dynamic process. Primary OA cannot be traced to any particular identifiable cause. In secondary OA, a known etiology or cause has been determined. We know osteoarthritis affects not only articular cartilage but also periarticular muscles, subchondral bone and ligaments, synovial membranes, and the entire joint capsule. The interplay of cellular, biochemical, and mechanical processes underlies the disease. Various risk factors have been identified and can be classified as modifiable and nonmodifiable. Modifiable risk factors of OA include obesity and joint trauma. Increased body weight has been correlated with increased risk of OA of the knee, but not the hip. Excess weight contributes to the biomechanical forces and stresses on the knee joints. The cascade of increased pain leading to decreased function and further worsening of obesity can be a difficult cycle to break. Weight loss and moderate amounts of activity improve symptoms of OA of the knee and improve overall health. Nonmodifiable risk factors are advancing age, sex, genetics, and joint location. Typically, the development of symptomatic OA occurs with increased age predominantly in the weight-bearing joints, although many women are affected by localized inflammation of the proximal and distal interphalangeal joints known as Bouchard and Heberden nodes, respectively. Approximately 80% of patients older than 75 years are affected by OA.

Epidemiologic studies provide support for a genetic component to the development of OA as well as the characteristic Heberden and Bouchard nodes. Studies in twins have also supported the influence of genetics and the development of OA. Multiple genes have been identified that are associated with increased risk for OA as well as some genetic mutations associated with OA of early onset. With the increasing development of isolating specific genotypes and pharmacogenomics, more targeted interventions could be implemented to arrest disease progression. OA is particularly more common in the hips and knees than in the ankle joint. Joint trauma can result in the evolution of OA. Biochemical and mechanical changes can occur, resulting in the characteristic joint pain and stiffness. The consequences are articular cartilage with less functionality and resultant characteristics of cartilage, joint capsule, and subchondral bone that are distinctively different from those of normal bone. Regular exercise and physical activity do not increase the risk of OA in normal joints and are necessary to maintain cartilage.[5]

The development of radiologic evidence of OA precedes the clinical symptoms; thus, the initial presentation may not always correlate with disease prognosis. Diminished ability of chondrocytes to maintain and repair articular cartilage has been correlated with resultant cartilage degradation. These age-related changes in chondrocyte function are associated with a decreased response to anabolic stimuli such as insulin-like growth factor-1 (IGF-1). Thus, the biochemical signal to spur production of proteoglycans and collagen that maintain the strength of cartilage decreases and results in an imbalance between breakdown and repair. The effect of age on chondrocyte apoptosis seems to be strongly related. Perhaps, because of occupational or recreational injury, men tend to have more OA before the age of 50.[5]

PATHOGENESIS

In the early stages of OA, changes occur that appear to begin the complex abnormalities seen in the joint capsule, subchondral bone and ligaments, periarticular muscles, and synovial membranes. Initial insult to the articular cartilage can result from repetitive damage with time. Alternatively, another theory has been proposed that examines articular damage after superficial or deep penetration injury. Either repetitive or traumatic injury to articular surfaces initiates the cascade leading to release of inflammatory cytokines (tumor necrosis factor [TNF], IL-1), nitric oxide, and enzymes that break down the extracellular matrix. The breakdown of extracellular matrix results in cartilage that is less elastic and less able to support joint loads, and stiffening of subchondral bone. The cartilage is less able to support forces, with diminished efficacy for providing joint lubrication and weight distribution across the joint. Cartilage is avascular, however, and contains chondrocytes that under normal conditions are responsible for cartilage breakdown and repair. In early osteoarthritis, chondrocytes attempt to repair joint damage by forming osteophytes, which try to stabilize the joint or alter the biochemical properties of cartilage. The formation of osteophytes may provide an increased surface area over which to distribute the forces across the joint. Cyst formation likely arises via synovial fluid pressure exerted on the fissures or other structural defects in subchondral bone.[5]

Early in the disease process, the water content of the cartilage is increased. However, this less viscous cartilage is structurally weaker than normal cartilage. There are many structural alterations that contribute to the weakened collagen network. One of the early changes is a smaller diameter of type II collagen, in comparison with that in the more structurally intact disease-free joint. With disease progression, the proteoglycan concentrations

diminish with shorter glycosaminoglycan side chains resulting in decreases of net aggregate proteins. Type I collagen within the extracellular matrix increases, and keratin sulfate concentrations decrease. Some of the biochemical changes are reflective of those produced in culture by immature tissue. The deposition of calcium crystals represents a curious finding. It is unknown whether calcium deposition has a direct involvement or is reflective of increased chondrocyte activity. Eventually, the initial water swelling of the cartilage is replaced by cartilage with reduced propensity to allow bone to distribute the force and slide on bone.[5] Distinct alterations in cartilage matrix metabolism favor catabolism. Chondrocytes are unable to maintain production of essential macromolecules necessary for healthy cartilage. However, the syntheses of those enzymes that break down the matrix are increased by the same chondrocytes. The enzymes that degrade proteoglycans and collagen are called aggrecanases and collagenases, respectively. The control of these enzymes is complicated by enzymatic activation of latent proteins and inactivation by proteinase inhibitors. In OA, the expression and production of proteinases is increased. Collagen is typically cleaved by matrix metalloproteinases (MMPs), MMP-1, MMP-8, and MMP-13. Most recently, the role of inflammation and inflammatory mediators produced by cartilage is being more closely investigated. Upregulated by IL-1 and TNF, MMPs cleave collagen and break down other important elements of the extracellular matrix. Ultimately, the imbalance between cartilage maintenance and degradation leads to erosion and eventual cartilage destruction.[5]

OVERVIEW OF DRUG THERAPY

The current treatment of OA is to provide analgesia allowing performance of activities of daily living (ADLs), facilitate participation in physical or occupational therapies, and recommend appropriate self-managed exercise programs. There are no disease-mitigating strategies that have demonstrated acceptable safety and efficacy in the treatment of OA. The initial treatment for OA pain and stiffness is acetaminophen given on a routine basis for a 2- to 3-week trial in doses typically less than 4 g/day or less than 3 g/day in patients older than 65 years, unless clinically contraindicated. Acetaminophen offers a considerable degree of safety over nonsteroidal anti-inflammatory drugs (NSAIDs) for mild-to-moderate OA disease. However, many clinical trials have demonstrated significantly better efficacy of NSAIDs as compared with acetaminophen in selected patients, such as those who present with both pain and inflammation, because acetaminophen lacks significant anti-inflammatory effects.[6–8] These patients are more likely to exhibit more moderate-to-severe disease.[5,9,10] Unintentional liver injury may result from overuse of acetaminophen above recommended doses, in combination with over-the-counter acetaminophen containing products, or the opioid–acetaminophen products available by prescription. A trial of a selective or nonselective NSAID would be a reasonable consideration in patients with inadequate response to acetaminophen or presenting with pain and inflammation. A careful risk and benefit analysis must be individualized for each patient starting an NSAID. Adverse events of GI bleeding, diminishing renal function, liver toxicity, and cardiovascular risk of the specific medication considered need to be carefully assessed and a plan for therapeutic monitoring implemented. Additionally, consideration of drug–drug interactions or drug–disease interactions is also warranted. Topical therapies may be therapeutic for selected patients unable to tolerate oral NSAIDs and are becoming more widely recommended by professional practice guidelines.[11,12] Topical therapies include capsaicin creams, capsaicin gels, capsaicin liquids, capsaicin lotions, capsaicin topical patches, lidocaine topical patch, lidocaine topical creams, ointments, and gels, diclofenac topical gel, diclofenac topical patch, and diclofenac topical solution. In patients presenting with effusions of the knee, aspiration of the affected joint and intra-articular injections of corticosteroids may be therapeutic once infectious etiologies have been ruled out. In patients with inadequate relief in symptoms and worsening functions, there are few alternatives outside of surgical interventions. Intra-articular injections of hyaluronic acid derivatives are the last of the conservative strategies before surgical interventions are considered. Tramadol may represent a useful option for many patients unless precluded due to seizures or misuse history or drug–drug interaction potential. There are currently no recommendations for the use of oral glucocorticoids in the treatment of OA. A trial of 6 months of glucosamine and chondroitin can be discussed with those patients interested in pursuing this type of therapy. The use of oral or transdermal opioids or opioid/acetaminophen combinations for pain management should be discouraged because of the limited evidence demonstrating benefit and the high potential for adverse drug reactions.

CLINICAL MANIFESTATIONS

Clinical Presentation of Osteoarthritis

CASE 43-1

QUESTION 1: R.T., a 64-year-old nonsmoking woman, presents to her primary-care physician reporting pain and stiffness in her right knee. The pain is usually worse in the morning and lasts for about 15 to 20 minutes and then subsides throughout the day. She reports some increased difficulty taking care of her grandchildren while her daughter is working. Her medical history is significant for hypothyroidism, hypertension, and hyperlipidemia. Social history is negative for tobacco and alcohol use. R.T. currently takes amlodipine 5 mg daily, levothyroxine 88 mcg daily, and simvastatin 40 mg daily. On physical examination, there is a varus misalignment of the knees. The right knee has no swelling or synovial effusions, and crepitus is noted on examination of passive motion. A radiograph shows right knee joint space narrowing with osteophyte formation at the joint margins.

Laboratory values and vital signs obtained at this visit include the following:

Blood pressure (BP), 135/78 mm Hg
Heart rate (HR), 80 beats/minute
Height, 64 inches
Weight, 205 pounds
BMI, 35.2 kg/m^2
Sodium, 140 mEq/L
Potassium, 4.5 mEq/L
Blood urea nitrogen (BUN), 10 mg/dL
Creatinine, 0.9 mg/dL
Estimated glomerular filtration rate (eGFR), 63 mL/minute
Thyrotropin (TSH), 3.08 mIU/mL
White blood cells (WBC), $5 \times 10^3/\mu L$
Red blood cells (RBC), $4.7 \times 10^6/\mu L$
Hemoglobin, 12.7 g/dL
Hematocrit, 38.2%
Uric acid, 5 mg/dL
C-reactive protein (CRP), 0.9 mg/dL
Erythrocyte sedimentation rate (ESR), 18 mm/hour
Anti-CCP antibodies, negative
Total cholesterol, 160 mg/dL
High-density lipoprotein (HDL), 45 mg/dL
What signs and symptoms suggestive of OA are present in R.T.?

CASE 43-1, QUESTION 2: How do the subjective and objective findings of OA correlate with disease pathogenesis in R.T.?

R.T. presents with unilateral right knee pain that is worse in the morning and subsides throughout the day. The OA diagnosis can be made by a good history and physical examination. Laboratory studies are not needed to confirm the diagnosis of OA, but a normal ESR rules out inflammatory conditions such as gout or septic arthritis. Radiographs demonstrate joint space narrowing that is consistent with OA. However, radiographs do not reliably assess disease severity.

The characteristic joint space narrowing as seen on radiograph without joint destruction is characteristic for OA. Osteophyte formation and bone rubbing against bone are most likely responsible for the pain, stiffness, and crepitus demonstrated on physical examination. Crepitus is an audible “crackling” sound that can be heard with passive or active movement of the joint. Instead of the opposing joint surfaces gliding past each other, the movement of the joint now creates the characteristic crunching or crackling sounds. Additionally, the varus misalignment contributes to the stress on the knee joint and some of the functional impairments R.T. reported to her primary-care physician. A varus misalignment is described as the patient in a standing position with his/her knees appearing further apart (bow-legged), and valgus is when the knees are closer together. Both of these deformities can affect a patient’s function and quality of life.

The clinical presentation of OA is usually unilateral pain and stiffness of the knee, hip, or cervical or lumbar spine; the distal interphalangeal joints generally are not painful. More often than not, OA tends to affect more than one joint. There are some distribution associations described between knee and hand OA and knee and hip OA. Elbows, wrists, and shoulders tend not to be affected by OA. Diagnostic criteria from the American College of Rheumatology (ACR) hip criteria have a sensitivity and a specificity of 91% and 89%, respectively, and a sensitivity of 91% and specificity of 86% for knee OA.[3] These criteria usually are not used in clinical practice outside of research studies. Clinical trials typically provide outcome data based on assessment tools such as the Western Ontario and McMaster Universities (WOMAC), predominantly used for knee OA. A WOMAC functional subscale exists to assess for functional disability.[13] Patients usually present to their primary-care provider with complaints of increased pain or stiffness lasting less than 30 minutes, usually in the morning or after periods of prolonged immobility. They usually will report decreases in their ADL, functional status, and overall health-related quality of life. Typically, household activities such as kneeling, stair climbing, and walking tend to be limited. The associated decrease in activities, range of motion, and overall physical activity contribute to muscle weakness and unsteadiness.

Problems with sleep and depression can occur, compromising attempts to lose weight, increase activity, and participate in physical or occupational therapy or in Tai Chi. Joint involvement can be characterized with swelling, easily recognized in the fingers and knees. Joints usually are tender when examined during active motion or application of pressure. Bursitis, tendonitis, muscle spasms, and torn meniscus can cause limitations in range of motion and need to be ruled out. Synovial effusions can be chronic but can also present during times of disease exacerbations. The patellar tap test or the wave test can elucidate joint effusions. Patients with advanced disease may present with the expected loss of cartilage, but also deformities in surrounding bone and soft tissue affecting the ligaments. Joint misalignment is common and contributes to joint unsteadiness. Fingers of patients with the characteristic Bouchard and Heberden nodes are misaligned. Muscle atrophy is demonstrated by simply measuring the circumference of the quadriceps muscles. The use of radiographs is usually not necessary for the diagnosis of OA, but rather is used to rule out conditions such as avascular necrosis, Paget disease of the bone, rheumatoid arthritis, or gouty arthropathies. However, radiographs can be useful to establish disease severity or monitor for disease progression. The clinical features described on radiographs that are characteristic of OA are joint space narrowing, osteophytes at the joint margins, and sclerosis of subchondral bone. As demonstrated in the above case study, R.T.'s knee radiograph revealed joint space narrowing with osteophyte formation.

An ultrasound can be useful for detecting or confirming joint effusion, popliteal cysts, or other erosive inflammatory conditions. Laboratory assessments are usually unnecessary, because the ESR and CRP are typically within reference ranges. Serum uric acid can help differentiate between similar inflammatory presentations. Synovial fluid aspiration is appropriate if septic or inflammatory arthritis is suspected. In the patient with OA, the WBC count is less than 2,000 µL, synovial fluid is clear, and crystals are absent. There are no relevant biomarkers of bone or cartilage remodeling that are used in the routine care of patients with OA. Magnetic resonance imaging (MRI) scans represent an exciting area of research for assessing cartilage, synovium, and bone, but are not routinely used in the diagnosis of OA.

CASE 43-1, QUESTION 3: Cytokines are involved in the pathophysiology of OA. Is it possible to modulate these cytokines and thereby slow or delay the disease process to benefit R.T. before her condition worsens?

The role of IL-1 and TNF in rheumatoid arthritis pathogenesis represented exciting discoveries that have led to highly effective disease remissions. However, in OA, the role of these cytokines in upregulating MMP and the exact mechanism that they play in the disease process have not been clearly elucidated and have not resulted in any disease-mitigating therapies.

TREATMENT OF OSTEOARTHRITIS

CASE 43-1, QUESTION 4: What nonpharmacologic therapies should be recommended in R.T.?

Nonpharmacologic Management of OA

Nonpharmacologic modalities are a primary strategy for OA treatment. As previously discussed, there are no interventions that effectively attenuate the disease process. Pharmacologic strategies have significant untoward effects and modest efficacy in the management of OA pain and disability. Patients typically have difficulty adhering to self-management, aerobic, or strength-training programs. Many times, nonpharmacologic strategies are not even attempted until pharmacologic interventions have failed or side effects necessitate discontinuation of the offending agent.

The ACR outlines a variety of patient education, self-management, weight loss, aerobic, and physical and occupational therapies.[14] A study in middle-aged patients with knee OA has demonstrated equivocal efficacy in comparing self-management with strength training and the combination of both programs. Outcomes assessed were pain, disability, and physical conditioning during the 2 years of the trial.[13] One clinical trial examined the comparison of NSAID therapy with quadriceps home exercise. Quality-of-life surveys and pain scores were not different between the groups reviewed in this small trial.[15] In older patients, Tai Chi has established efficacy through randomized controlled trials in the treatment of knee OA. Wang et al.[16] demonstrated the beneficial effects of Tai Chi not only in improving physical function and lessening

---

pain in patients with OA, but also in having a positive effect on their mental health and overall quality of life. Trial limitations included a small sample size (40 patients) and 3-month study duration. It is unknown whether those demonstrated benefits were sustained. Patients can be referred to the Arthritis Foundation website (http://www.arthritis.org) for further information on various programs or activities in their areas. The Osteoarthritis Research Society International (OARSI) reiterates the effectiveness of nonpharmacologic interventions of self-management, weight loss, exercise, referral to physical therapy, and effective use of bracing for varus or valgus misalignments.[11,12] Nonpharmacologic interventions remain the most effective, yet underutilized, interventions for the treatment of OA.[11,17]

R.T. should be encouraged to lose weight and participate in either self-management or a structured exercise program that includes aerobic and strength-training exercises. Additionally, R.T. should be encouraged to participate in local Tai Chi classes. Weight loss should be the primary goal in obese patients with OA of the knee. Exercise improves muscle strength and helps prevent falls. The use of knee bracing may offer some degree of support in patients with misalignments of the knee joints.

CASE 43-1, QUESTION 5: What is the initial pharmacologic treatment recommendation for R.T.?

Pharmacologic Management of Osteoarthritis

A trial of acetaminophen 1,000 mg PO 3 to 4 times a day should be attempted for 2 to 3 weeks. More aggressive medications are usually reserved for those patients who have failed acetaminophen. Medications such as NSAIDs can increase blood pressure, cause GI ulceration, inhibit renal prostaglandins that are vasodilatory and, therefore, diminish renal function, and potentially increase cardiovascular risks. Given R.T.'s past medical history of peptic ulcer disease and lack of knee inflammation on physical examination, the initial trial of acetaminophen is warranted.

ACETAMINOPHEN

Acetaminophen remains the first choice for the treatment of mild-to-moderate OA of the hands and knees. Clinical practice guidelines from the American College of Rheumatology (ACR), the American Academy of Orthopedic Surgery (AAOS), the European League Against Rheumatism (EULAR), and the Osteoarthritis Research Society International (OARSI) differ in their strength of recommendation, dosing, and length of therapy for acetaminophen.[11,14,18,19]

Chronic acetaminophen use in patients who consume more than three alcoholic drinks per day can increase risk of GI bleeding and elevations of liver enzymes.[20] A 12-week randomized, controlled trial reported in 2007 that extended-release acetaminophen 3,900 mg/day was safe, well tolerated, and more effective than 1,950 mg/day in patients with hip and knee OA.[21] More recently, it has been suggested that select patients presenting with both pain and inflammation without contraindications begin an initial trial with an NSAID instead of acetaminophen.[12]

CASE 43-1, QUESTION 6: What is the role of topical agents in the treatment plan for R.T.?

TOPICAL THERAPY

There are numerous prescription and nonprescription topical analgesics available, containing capsaicin, diclofenac, lidocaine, or methyl salicylate. Both the ACR and OARSI practice guidelines conditionally recommend topical NSAID therapy as a potential first-line therapy for joint-specific OA.[11,14] Topical capsaicin cream is applied to the hands or knees 3 to 4 times daily. If used, R.T. should be counseled regarding proper application, initial burning and sensitivity reactions, and expectations of benefits that may take up to a few weeks. There are no systemic effects or drug interactions with topical capsaicin cream.[11]

Currently, three topical diclofenac products are commercially available in the United States, including a 1% gel, a 1.5% solution, and a 1.3% patch. Topical diclofenac 1% gel, alone or in combination with oral acetaminophen, represents another therapeutic option. Topical diclofenac 1% gel is indicated in the treatment of OA of the upper extremities such as the hands, elbows, and wrists, and the lower extremities such as ankles, feet, and knees. The gel is applied according to "dosing cards" in either 2-g or 4-g measurements. The dose for the upper extremities is 2 g 4 times a day and 4 g 4 times daily to the lower extremities.[22]

Diclofenac topical solution 1.5% w/w in dimethyl sulfoxide, USP (DMSO) 45.5% w/w represent another treatment option for the signs and symptoms of OA of the knee. In two, 12-week, randomized, placebo-controlled trials, oral and topical diclofenac solution was equivocal for the outcome measures of pain and physical function.[23,24] Patients receiving the topical solution reported minor skin irritation, but fewer GI symptoms and abnormal liver function tests than those patients receiving oral diclofenac.

The diclofenac 1.3% patch, although available, is indicated only for the treatment of acute pain due to musculoskeletal sprains and strains.

CASE 43-1, QUESTION 7: What monitoring parameters would be appropriate for R.T.?

Although improved tolerability and decreased toxicity profiles appear promising for topical NSAIDs, the warnings about typical NSAID-related adverse effects are similar for oral and topical agents.[25] Data are lacking for true upper gastrointestinal bleed or cardiovascular event risk with topical versus oral administration. Outside of short-term efficacy trials, the risk for systemic complications with chronic therapy has not been investigated. Additionally, limited comparative efficacy data exist comparing topical diclofenac with other oral NSAIDs or topical capsaicin. Oral and topical NSAIDs should not be used concomitantly unless potential benefit greatly outweighs the risk due to reports of increased incidence of rectal bleeding and abnormal laboratory findings when used together.[26] The combination of acetaminophen and topical diclofenac may be therapeutic for some patients while avoiding other combinations with a higher degree of untoward effects. This combination, however, has yet to be evaluated in the rigor of randomized trials. The risk of significant GI bleeding would be theoretically less with topical preparations as a result of less systemic absorption.[12,23,24,27] In a 2010 systematic review, oral and topical NSAIDs were noted to have similar rates for discontinuation because of a high incidence of topical reactions with the latter.[28] It is unclear whether these skin reactions are caused by the type of formulation, vehicle, or other ingredients in the preparation.

R.T. does not have a history of liver disease or hepatitis C, so a short trial of acetaminophen does not require any monitoring for medication safety. However, it would be important to ask her to keep a daily pain log and complete a comfort assessment on her next visit. These tools are freely available online from multiple sources. This will engage the patient in her own care as well as provide the clinician with information regarding baseline data, medication efficacy, and the impact of medication on functional impairment. Additionally, limitations or improvements in ADLs and instrumental activities of daily living (IADLs) can provide useful information in helping the clinician determine whether any changes in the plan of care need to occur.

NSAIDS AND OTHER PHARMACOLOGIC TREATMENT

CASE 43-2

QUESTION 1: S.L., a 67-year-old woman, presents to her primary-care physician with increased pain and stiffness in her left knee. S.L. reports her left knee as "weak," and she has difficulty getting out of bed in the morning and after sitting on the recliner for some time. She has tried acetaminophen 1,000 mg 4 times daily for 1 month without adequate relief. She also takes metoprolol succinate 50 mg daily, lisinopril 20 mg daily, ranitidine 150 mg twice daily, and citalopram 20 mg daily. Her medical history includes hypertension, osteopenia, depression, gastroesophageal reflux disease, osteoarthritis, and a right knee replacement 2 years ago. Her recent laboratory values and vital signs include the following:

BP, 160/78 mm Hg
HR, 76 beats/minute
Height, 66 inches
Weight, 190 pounds
BMI, 30.7 kg/m^2
Sodium, 145 mEq/L
Potassium, 4.8 mEq/L
BUN, 16 mg/dL
Creatinine, 1.2 mg/dL
eGFR, 48 mL/minute
WBC, 4.5 × 10^3/μL
RBC, 4.2 × 10^6/μL
Hemoglobin, 12.1 g/dL
Hematocrit, 36.6%

Select and recommend a medication to provide adequate pain relief for S.L.

In this patient who has failed an adequate trial of acetaminophen, therapeutic options include celecoxib, a nonselective NSAID, tramadol, or an opioid analgesic. There are no data to suggest any particular NSAID is more effective than another.[29] S.L. does not have any known history of coronary heart disease or peptic ulcer disease. On the basis of the risk factors identified in Table 43-1, S.L. has one risk factor of age, placing her at moderate risk for GI ulceration. Data suggest appropriate treatment of Helicobacter pylori, if present, reduces the risk of GI ulceration in patients taking NSAIDs chronically.[30] Therefore, if the decision is made to recommend a nonselective NSAID, then ranitidine would need to be discontinued because of a lack of protection against gastric ulcers, and a proton-pump inhibitor (PPI) such as omeprazole should be initiated to prevent GI bleeding. Either option would represent a reasonable therapeutic recommendation.

Table 43-1

Recommendations for NSAID Selection Based on Gastrointestinal and Cardiovascular Risks[30]

Risk Category	Low GI Risk	Moderate GI Risk	High GI Risk
	0 risk factors	1–2 risk factors	Multiple risk factors, history of previous ulcer events, or continued use of corticosteroids or

			anticoagulants
Low CV risk	NSAID alone	NSAID + PPI/misoprostol	Alternative therapy or COX-2 + PPI/misoprostol
High CV risk (low-dose aspirin required)	Naproxen + PPI/misoprostol	Naproxen + PPI/misoprostol	Alternative therapy recommended

COX-2, cyclooxygenase-2 inhibitor; CV, cardiovascular; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton-pump inhibitor.

Table 43-2

Relative Selectivity of Cyclooxygenase Inhibitors[67]

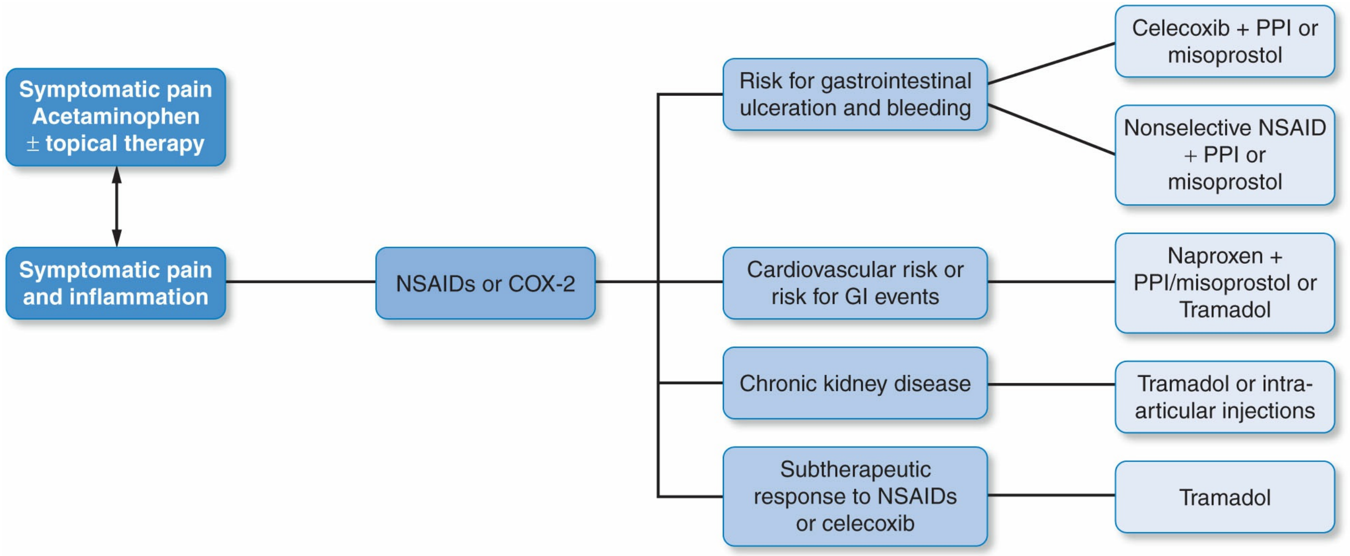
5- to 50-fold COX-2 Preferential	<5-fold COX-2 Preferential	COX-1 Preferential
Etodolac Meloxicam Celecoxib	Diclofenac Sulindac Meclofenamate Piroxicam Diflunisal	Fenoprofen Ibuprofen Tolmetin Naproxen Aspirin Indomethacin Ketoprofen Flurbiprofen Ketorolac

Based on log IC_{80} inhibition ratios COX-2/COX-1.

For those patients with insufficient pain relief from acetaminophen or topical agents, an oral NSAID should be considered. As with any decision regarding pharmacotherapy, the safety and efficacy of the chosen therapy needs to be evaluated in the context of a patient's specific case. The historical perspective and the knowledge of increased cardiovascular risk versus GI safety with COX-2 agents have had a tremendous impact on the use of these agents in clinical practice. Currently available NSAIDs have comparatively unique characteristics in terms of their ability to inhibit COX-1 (constitutive) and COX-2 (inducible). See Table 43-2 for selectivity of COX-2 inhibition.

Patients at increased risk for cardiovascular disease include those with unstable angina, a history of myocardial infarction, coronary artery bypass surgery, ischemic stroke, or a high Framingham risk score.[31] Some clinicians have recommended the addition of low-dose aspirin 81 mg to attenuate the increased risk of cardiovascular disease; however, this practice has not been the primary focus of vigorous clinical trials. The addition of aspirin can potentially increase the risk of GI ulceration and compromise cardioprotection.[32] Additionally, randomized controlled studies have not clearly demonstrated the efficacy and safety of this approach.[31,33]

In a 52-week double-blind study comparing the cardiovascular outcomes of patients with OA exposed to ibuprofen, naproxen, or lumiracoxib, several key findings emerged. First, ibuprofen users taking aspirin had the highest risk of cardiovascular outcomes and heart failure in comparison with lumiracoxib. This supports concerns that ibuprofen can competitively interfere with the ability of aspirin to inhibit platelet aggregation.[34] Second, patients taking naproxen without aspirin had the best safety profile with regard to cardiovascular outcomes. Whether or not naproxen has the lowest risk for cardiovascular side effects has not been clearly elucidated. In fact, recent analysis from the Women's Health Initiative suggests naproxen, in addition to NSAIDs with cyclooxygenase-2 preferential inhibition, exhibits increased risk for cardiovascular events.[35] Conflicting data regarding dose, duration of therapy, and methodological differences in trials have not yet produced clear and concise evidence.[36] Lastly, heart failure was observed more frequently in patients taking ibuprofen than in patients receiving lumiracoxib or naproxen.[37] In a recent AHRQ report, celecoxib has been reported to increase the risk for myocardial infarction, particularly at higher doses.[27] Other studies have failed to exhibit this finding.[38] In summary, for patients with low cardiovascular risk and moderate-to-higher risk for GI bleeding, a recommendation can be made for once-daily celecoxib or NSAID plus PPI or misoprostol. However, in patients with a higher risk for cardiovascular disease, consider the use of tramadol or naproxen, or nonacetylated salicylates (e.g., diflunisal or salsalate) with careful monitoring of blood pressure and renal function (use of aspirin concurrently with naproxen may need further assessment for clinical need).[39,40]



Symptomatic pain
Acetaminophen
± topical therapy
Symptomatic pain and inflammation
NSAIDs or COX-2
Risk for gastrointestinal ulceration and bleeding
Celecoxib + PPI or misoprostol
Nonselective NSAID + PPI or misoprostol
Cardiovascular risk or risk for GI events
Naproxen + PPI/misoprostol or Tramadol
Chronic kidney disease
Tramadol or intra-articular injections
Subtherapeutic response to NSAIDs or celecoxib
Tramadol

Figure 43-2 Overview of pharmacologic therapy for treatment of osteoarthritis. (Adapted from multiple references.)[11,12,14,18,30]

CASE 43-2, QUESTION 2: What monitoring parameters would be appropriate for this pharmacologic treatment recommendation for S.L.?

Many clinicians recommend checking a basic metabolic panel and complete blood count with differential 2 to 4 weeks after starting NSAIDs in older patients.

Depending on the initial laboratory results, testing can occur every 3 to 4 months, thereafter for the next year. The risk for GI adverse events decreases after 1 month, but is always present. Liver function should be checked regularly during the first year of treatment and periodically thereafter. Patients with significant comorbidities may need more stringent follow-up and monitoring. Analgesic efficacy is best evaluated using a consistent systematic assessment approach. If S.L. is to remain on chronic NSAID therapy, then monitoring her liver and renal function every 3 months for the first year would be reasonable.

CASE 43-2, QUESTION 3: One week later after starting naproxen 500 mg twice daily, S.L. has been adherent with therapy and had a basic metabolic panel completed before this office visit. S.L. reported a decrease in pain since she had been started on naproxen. Laboratory values and vital signs obtained at this visit include the following:

BP, 155/78 mm Hg
HR, 88 beats/minute
Height, 66 inches
Weight, 194 pounds
BMI, 30.7 kg/m^2
Sodium, 135 mEq/L
Potassium, 5.5 mEq/L
BUN, 40 mg/dL
Creatinine, 2.2 mg/dL
RBC, 4.7 × 10^6/μL
Hemoglobin, 10.3 g/dL
Hematocrit, 33.8%
What changes, if any, need to be made with her OA therapy?

Gastrointestinal ulceration and bleeding remain a cardinal concern when evaluating patients for treatment of chronic pain in OA. The addition of a PPI to a nonselective NSAID has been proposed as a less expensive alternative to the more expensive COX-2 inhibitor agent, celecoxib. Older patients with OA have comorbidities requiring aspirin in addition to a COX-2 or NSAID. Goldstein et al.[41] compared celecoxib and aspirin with naproxen, lansoprazole, and aspirin with endoscopically diagnosed ulcers after 12 weeks of therapy. Gastrointestinal ulceration rates were found to be statistically insignificant among groups. In contrast, another randomized controlled trial compared celecoxib with diclofenac and omeprazole in patients with OA and rheumatoid arthritis for 6 months. The risk for GI bleeding was evaluated across the small bowel.[42]

There were less lower and upper gastrointestinal events in the celecoxib treatment group. Consideration of clinically significant anemia not responsive to acid-suppressive interventions (PPIs) distal to the duodenum may provide the clinician with more evidence in patients at increased risk for GI ulceration and bleeding. The results are suggestive of better clinical outcomes with celecoxib versus diclofenac and omeprazole.[42] These results are interesting because they contrast with results found in previous studies. Additionally, it is unknown whether the results found with diclofenac can be extrapolated to naproxen or other NSAIDs. Clearly, further investigation is warranted before changes in practice are suggested. A meta-analysis based on epidemiologic studies illustrates the safety of celecoxib with regard to risk for GI ulceration and bleeding. Additionally, NSAIDs with long half-lives and slow-release formulations were found to demonstrate higher risks for GI events. Higher relative risk (RR) for GI bleeding (>5) was associated with naproxen, indomethacin, ketoprofen, ketorolac, and piroxicam, whereas a lower RR (<5) was found for ibuprofen, diclofenac, celecoxib, meloxicam, rofecoxib, and aceclofenac.[43]

The most frequent reason for withdrawal from this year-long trial was GI adverse events for both medications; however, abnormal liver function tests caused more patients taking diclofenac to withdraw from the study.[42] Diclofenac is associated with elevations in alanine aminotransferase and aspartate aminotransferase levels; however, increases in aminotransferase levels alone are not predictive of liver injury. The FDA recognizes increases in both bilirubin and aminotransferase levels as surrogate markers for drug-induced liver disease. In a study completed by Laine et al.,[44] the risk of hospitalization associated with diclofenac therapy is described as relatively rare (0.023% per 100,000 patient-years). The low rate of hospitalization may be secondary to clinical vigilance. This study also found elevations in liver function test concentrations to occur in the initial 4 to 6 months of therapy and does not necessarily parallel clinical significant liver injury.

Table 43-3

Recommendations for Nonpharmacologic and Pharmacologic Treatments by OA Site[14]

OA Site	Nonpharmacologic Recommendations	Pharmacologic Recommendations
Hand	Evaluate ability to perform ADLs Instruct in joint protection techniques Provide assistance devices, as needed, to help patients perform ADLs Instruct in use of thermal agents for relief of pain and stiffness Provide splints for patients with trapeziometacarpal joint OA	Topical capsaicin Topical/oral NSAIDs, including trolamine salicylate and COX-2 selective inhibitors (patients ≥75 years should use topical NSAIDs) Tramadol **Discourage** Intra-articular therapies (corticosteroids, hyaluronates) Opioid analgesics
Knee	**Participate in aerobic and/or resistance land-based exercise** **Participate in aquatic exercise** **Lose weight (if overweight)** Participate in self-management programs ± psychosocial interventions Use thermal agents and manual therapy in	Acetaminophen Oral/topical NSAIDs Patients ≥75 years should use topical NSAIDs Patients with h/o upper GI ulcer should use COX-2 selective inhibitor or nonselective NSAID + PPI

	combination with PT-supervised exercise Use medially directed patellar taping Participate in tai chi programs Receive walking aids, as needed If lateral compartment OA, wear medially wedged insoles If medial compartment OA, wear laterally wedged subtalar strapped insoles Some moderate–severe pain patients are candidates for acupuncture or TENS	Patients with upper GI bleed ≤1 year ago should use COX-2 selective inhibitor + PPI Tramadol Intra-articular corticosteroid injections Opioids or duloxetine for patients who failed all other therapies and are not candidates for total joint arthroplasty **Discourage** Chondroitin sulfate Glucosamine Topical capsaicin
Hip	**Participate in cardiovascular and/or resistance land-based exercise** **Participate in aquatic exercise** **Lose weight (if overweight)** Participate in self-management programs ± psychosocial interventions Use thermal agents and manual therapy in combination with PT-supervised exercise Receive walking aids, as needed	Acetaminophen Oral NSAIDs Tramadol Intra-articular corticosteroid injections Opioids for patients who failed all other therapies and are not candidates for total joint arthroplasty **Discourage** Chondroitin sulfate Glucosamine

TRAMADOL AND OPIOIDS

In the week that has passed, there has been an increase in potassium, serum creatinine, and BUN. COX-2 preferential and nonselective inhibitors have the same potential to cause adverse renal effects. Naproxen should be discontinued, and additional monitoring should be ordered to ensure laboratory values return to baseline. The drop in hemoglobin may also be concerning, and appropriate follow-up with either endoscopy or stool occult blood testing should be considered.

CASE 43-2, QUESTION 4: S.L. has seen commercials on television advertising “knee injections.” Describe the available therapeutic options.

In many patients with contraindications or subtherapeutic response to acetaminophen, NSAIDs, or COX-2 inhibitors, a trial of tramadol should be considered. Therapeutic alternatives for analgesia are now limited to opioids or tramadol for S.L. Tramadol is a centrally acting analgesic that binds to the mu-opioid receptor and also inhibits the uptake of norepinephrine and serotonin.[45] The ACR recommends tramadol in those patients who have failed or have contraindications to NSAIDs.[14] Tramadol should not be used in patients with a history of seizures or receiving medications with serotonergic activity and requires dose adjustment with diminished renal function.[45,46] Tramadol can be used with acetaminophen, and the combination can be therapeutic.[47] However, she is taking citalopram for depression, and there is a potential drug interaction with tramadol; therefore, this combination should be judiciously considered. Opioid/acetaminophen combinations may be a short-term option in the interim while S.L. is being evaluated for intra-articular injection of either corticosteroid or viscosupplementation (hyaluronic acid injection) by her physician.

In patients in whom the use of tramadol is ineffective or contraindicated, the use of an opioid or opioid/acetaminophen combination can be considered.[48] Side effects from opioids include constipation, confusion, hallucinations, respiratory depression, tolerance, and addiction. A recent Cochrane review evaluated the use of oral and transdermal nontramadol opioids in the treatment of OA of the hip and knee.[49] Although the findings did conclude opioids are effective, their modest benefits are outweighed by their side effect profiles and should thus be avoided. Randomized, placebo-controlled studies have pointed to the efficacy and tolerability of transdermal buprenorphine with or without concurrent acetaminophen in the treatment of hip or knee OA, although long-term safety cannot be concluded at this time.[50,51]

DULOXETINE

Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of chronic musculoskeletal pain,

---

in addition to several other indications. In a 13-week randomized, double-blind, placebo-controlled trial involving 231 patients, duloxetine demonstrated statistically significant reductions in osteoarthritic pain of the knee.[52] The magnitude of difference in average pain between duloxetine and placebo in the reported mean end points and the mean change from baseline was modest, yet the tolerability and adverse effect profile of this medication are preferable to other potential treatment modalities. S.L. is currently receiving citalopram for the treatment of major depressive disorder. The risk-to-benefit analysis of switching citalopram to duloxetine has many considerations. The treatment of the depression and the significant medical history of the patient need to be carefully assessed. S.L. has a past medical history of recurrent depression resistant to several different medications and has been stable for the last year on citalopram. Next, tolerability and cost need to be evaluated because duloxetine may have a higher copay than citalopram, despite both agents’ availability as a nonbranded product. Should S.L. be switched to duloxetine for treatment of OA-related pain and depression, she should be counseled on the risk for transient headaches, nausea, and less frequently diarrhea. Liver transaminases are also recommended for periodic monitoring. Specific education regarding expected treatment results should also be provided because the onset of analgesia with duloxetine may be delayed following initiation. Given her concurrent diagnosis of depression, her mood should be reassessed frequently during the transition.

Intra-Articular Therapy

Ultimately, many patients fail oral or topical therapies, and intra-articular (IA) injections represent the last conservative efforts before surgical intervention for OA of the knee. Aspiration of synovial fluid and injections of glucocorticoids or viscosupplementation of hyaluronic acid are strategies that have been offered to patients with severe knee OA. Injections of triamcinolone or methylprednisolone with lidocaine 1% have been shown to be effective for approximately 4 to 8 weeks. Typically, IA glucocorticoids are given no more frequently than every 3 months. Side effects include a paradoxical localized inflammatory reaction.[53]

In a small multicenter, randomized trial, the safety and efficacy of IA treatment with hyaluronic acid in OA of the knee was demonstrated. However, there was a rather large placebo response and a small effect size with treatment in this trial.[54] In a 2005 meta-analysis, intra-articular hyaluronic acid supplementation did not demonstrate clinical efficacy in OA of the knee.[55] In contrast, a more recent Cochrane review found intra-articular injection of hyaluronic acid products to be effective and provide more sustained clinical effects than intra-articular injections of glucocorticoids. The authors acknowledged considerable product variability and corresponding times to clinical response.[56] A 2009 multicenter, randomized, placebo-controlled trial did not find any efficacy of hyaluronic acid in hip OA.[57] A meta-analysis reviewed studies of both intra-articular corticosteroids and hyaluronic acid in the treatment of OA of the knee. Seven studies including 606 subjects were included. Results suggest IA corticosteroids are comparatively more effective from baseline to week 4, after which IA hyaluronic acid appears to have greater durability of effect.[58]

CASE 43-2, QUESTION 5: Two years have passed, and S.L. has now failed all conservative strategies including intra-articular injections into her knee. After discussing all of her options with her physician, S.L. is referred to an orthopedic surgeon for elective left total knee replacement. She is awaiting discharge from the acute care hospital, pending transfer to a short-term rehabilitation facility to facilitate her return to home, and resumption of her previous level of function. S.L.'s current medications are metoprolol succinate 50 mg daily, lisinopril 20 mg daily, citalopram 20 mg daily, enoxaparin 30 mg subcutaneously twice daily, oxycodone CR 10 mg every 12 hours, senna/docusate one tablet twice daily, and oxycodone/acetaminophen 5 mg/325 mg one tablet every 4 hours as needed for moderate pain and two tablets every 4 hours as needed for severe pain. S.L. asks you, as the counseling pharmacist, why she still needs "shots in the belly?"

The American College of Chest Physicians (ACCP)' highest level of evidence for elective knee arthroplasty recommends low-molecular-weight heparin, fondaparinux, dabigatran, apixaban, rivaroxaban or warfarin (international normalized ratio [INR] goal of 2.5) for patients in whom a risk for significant bleeding does not exist. A minimal duration of therapy is for 10 days after surgery and up to 35 days for some patients.[59] It is important to educate S.L. with this information, providing the reason for enoxaparin is to prevent blood clots in her legs or lungs. In cases in which the creatinine clearance is less than 30 mL/minute, the appropriate dosage of enoxaparin would be 30 mg subcutaneously once daily.[60]

CASE 43-2, QUESTION 6: How long will S.L. need oxycodone CR and oxycodone/acetaminophen therapy?

Patients typically need the sustained-release dosing of their opioid analgesic given on a routine schedule only while undergoing aggressive physical and occupational therapy immediately after orthopedic surgery. By the time most patients return to their home environments, the use of as-needed dosing of opioid/acetaminophen combinations may be necessary for the completion of the short-term rehabilitation process. However, the long-term use of opioids in the treatment of chronic pain should be discouraged unless the benefits greatly outweigh the risks.

Comorbid Conditions in the Elderly

CASE 43-3

QUESTION 1: L.P. is a 76-year-old woman who was recently admitted to the hospital for elective right total hip replacement. She had failed all previous conservative interventions. Her medical history is significant for type 2 diabetes, hypertension, dyslipidemia, OA left knee and right hip, a right knee replacement 2 years ago, coronary artery disease, and history of myocardial infarction 1 year ago. Medications include glipizide 10 mg daily in the morning before breakfast, metformin 850 mg twice daily, lisinopril 20 mg daily, atorvastatin 40 mg daily, metoprolol succinate 100 mg daily, rivaroxaban 10 mg once daily with dinner, aspirin 81 mg once daily, celecoxib 200 mg once daily, and oxycodone/acetaminophen 5 mg/325 mg one tablet every 4 hours as needed for right hip pain. Identify L.P.'s risks associated with COX-2 inhibitor use.

The risks associated with nonselective NSAID or COX-2 inhibitor use in older adults with comorbid coronary artery disease include increased blood pressure, heart failure, and worse cardiovascular outcomes. Additionally, diminished renal function and gastrointestinal bleeding risks are relevant and require careful follow-up and monitoring. The lowest effective nonselective NSAID or COX-2 inhibitor dose for the shortest duration would possibly be recommended in situations where continued therapy is clinically indicated.

CASE 43-3, QUESTION 2: Identify any drug–drug interactions that would be clinically significant relative to L.P.'s prophylaxis for deep vein thrombosis after hip replacement surgery.

Caution is encouraged when combining medications to rivaroxaban that may increase the risk of bleeding.[61] In this case, LP requires aspirin for cardiovascular protection after the myocardial infarction. Additionally, celecoxib was added for pain management following hip replacement surgery. The addition of antiplatelet agents and NSAIDs to oral anticoagulant therapy increases the risk for bleeding. A careful evaluation of the risks and benefits of combination therapy would suggest discontinuation of the COX-2 inhibitor.

Dietary Supplements

Dietary supplements offer patients an alternative to prescription medications. Some patients often either fail multiple prescription drugs or have intolerable side effects. Others confuse dietary supplements with natural products and consider them safer than traditional medications. In the case of OA, the role of glucosamine, chondroitin, and the combination products has represented such an alternative to many patients. As with any OTC dietary supplement, the vigor of product consistency and standardization are not equal to FDA requirements for legend drugs. Researchers have found in evaluating the use of glucosamine, chondroitin, and the combinations in OA of the knee that they were all ineffective in reducing pain. However, it is worth noting that treatment effects were more pronounced in the subgroup of patients with moderate-to-severe reports of pain. Also, this trial included a celecoxib treatment group that also did not reach statistical significance with regard to primary outcomes measured.[62] Similar findings were published, concluding the lack of efficacy with glucosamine in treatment of OA of the hip as well as degenerative lumbar OA.[63–65] More recently, in a double-blind, multicenter trial, the combination of glucosamine and chondroitin was compared with celecoxib in patients with osteoarthritis of the knee.[66] The results of this trial in approximately 600 patients demonstrated noninferiority of the glucosamine with chondroitin compared to celecoxib after 6 months for the primary outcome of reduced pain.

Nontraditional alternatives for the pain, stiffness, and discomfort of OA are few and certainly lack the vigor of large-scale, long-term, clinical trials. However, in selected patients who wish to try glucosamine/chondroitin, a time-limited trial can be considered in patients who fail or refuse more traditional approaches to pharmacologic management. However, a general recommendation cannot be made for all patients.

Rheumatoid Arthritis

Steven W. Chen, Rory E. Kim, and Candace Tan

CORE PRINCIPLES

		CHAPTER CASES
1	Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder characterized by potentially deforming polyarthritis and a wide spectrum of extra-articular manifestations. Diagnosis of RA is based on joint involvement, serology, acute-phase reactants, and symptom duration.	**Case 44-1 (Questions 1, 2)**
2	Treatments for RA include nonpharmacologic (heat or cold therapy, range-of-motion [ROM] exercises, physical therapy, and occupational therapy) and pharmacologic options (nonsteroidal anti-inflammatory drugs [NSAIDs], synthetic [conventional and targeted] and biologic disease-modifying antirheumatic drugs [DMARDs], and corticosteroids). NSAIDs are for symptom management only and must be used cautiously, if at all, because of serious health risks, including gastrointestinal complications and thromboembolic cardiovascular events.	**Case 44-1 (Questions 3–5)** **Case 44-2 (Question 1)** **Case 44-3 (Questions 1, 2)** **Case 44-4 (Question 1)** **Case 44-5 (Questions 1–3)**
3	Owing to the destructive nature of the disease, DMARDs should be initiated as soon as possible once diagnosis has been established. Methotrexate is the most common selection because of efficacy, safety, rapid onset, and cost-effectiveness. Other traditional DMARDs and combinations of traditional DMARDs are selected based on disease severity, disease duration, and the presence of poor prognostic indicators. Regardless of the DMARD chosen, all require diligent monitoring.	**Case 44-5 (Questions 4–7)** **Case 44-6 (Questions 1–7)** **Case 44-7 (Questions 1–5)**
4	Patients with RA, who experience an inadequate response to traditional DMARD monotherapy or intolerable adverse effects, should consider the addition of or switching to a biologic DMARD. Diligent monitoring is also critical with biologic agents owing to the risk of serious adverse effects such as infections and lymphoma.	**Case 44-7 (Questions 6–8)** **Case 44-8 (Question 1)** **Case 44-9 (Question 1)**
5	Corticosteroids when used judiciously at the lowest effective doses and for limited duration, are very effective at quickly controlling inflammation while awaiting onset of DMARD therapy. Although systemic corticosteroids can be prescribed for short-term flares of RA disease activity, intra-articular corticosteroid injections are very effective at managing flares that are limited to a few joints and are not associated with the adverse effects of systemic therapy.	**Case 44-10 (Questions 1, 2)**
6	Juvenile idiopathic arthritis (JIA) describes an assortment of arthritis	**Case 44-11 (Questions 1, 2)**

	conditions affecting children and adolescents. Symptoms of JIA, such as joint inflammation and ROM limitation, are present before 16 years of age. As in RA, the diagnosis of JIA is based on clinical manifestations, and all infectious, traumatic, and other etiologies must be ruled out.	
7	Many nonpharmacologic treatment options are also available to supplement JIA pharmacologic therapy, including exercise, massage, and physical and occupational therapies.	**Case 44-11 (Question 3)**
8	Pharmacologic treatment options for JIA include NSAIDs, traditional and biologic DMARDs, and corticosteroids.	**Case 44-11 (Questions 4–9)** **Case 44-12 (Question 1)** **Case 44-13 (Questions 1, 2)**

EPIDEMIOLOGY

Arthritis refers to more than 100 different joint diseases causing swelling, pain and damage to joints and connective tissue.[1] Rheumatoid arthritis (RA) is the most common chronic inflammatory arthritis and is characterized by potentially deforming polyarthritis and a wide spectrum of extra-articular manifestations resulting from abnormal systemic immune response. It has an estimated worldwide prevalence of 0.5 to 1%, although rates vary between geographic regions.[2,3] In the United States alone, RA afflicts 1.3 million adults, occurring 2 to 3 times more often in women than in men.[3,4] RA prevalence increases with age, with the average age increasing from 63.3 years in 1965 to 66.8 years in 1995. These patterns predict that RA-associated morbidity, mortality, and disability will rise in future years, especially as the United States' baby boomer generation ages.[4]

ETIOLOGY

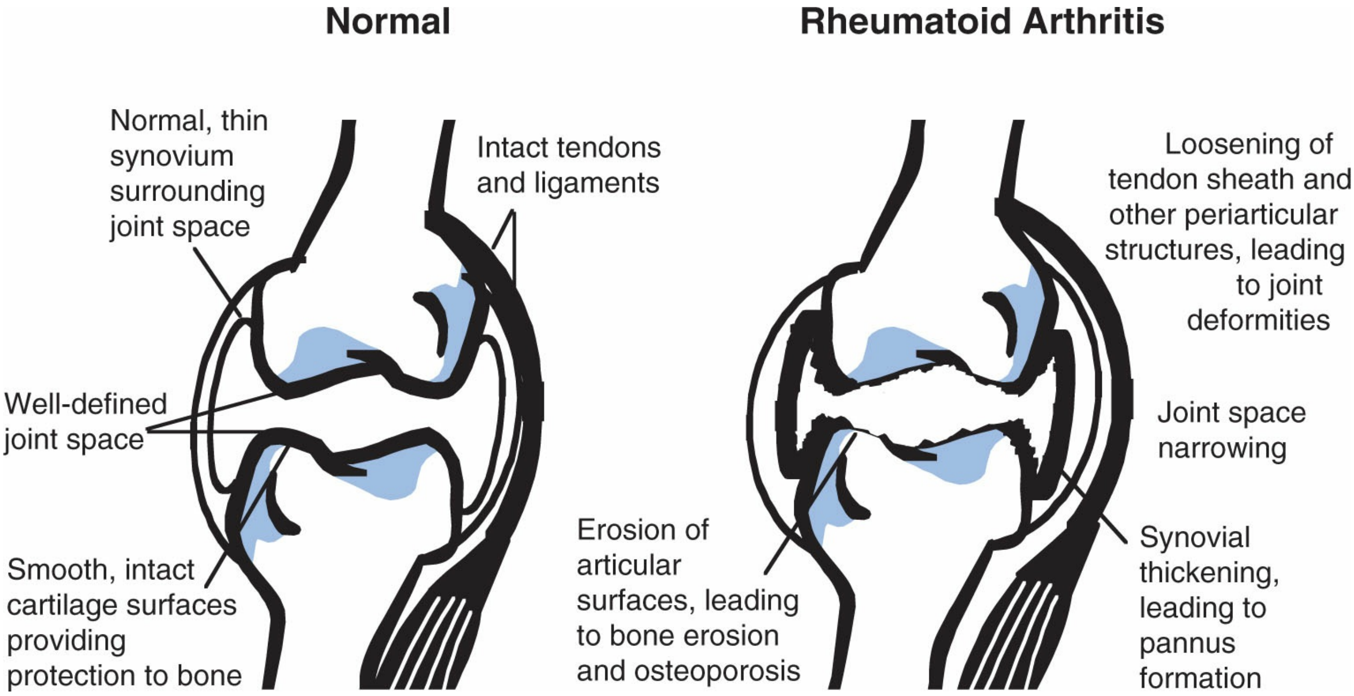
The exact etiology of RA is unknown, but like many autoimmune diseases it involves interplay among multiple factors including genetic susceptibility, environmental influences, and effects of advancing age on somatic changes in the musculoskeletal and immune system.[3] The onset of RA likely starts years before clinical symptoms develop with activation of specific genes, resulting in innate immunity activity leading the cascade of events.[3] It is suspected that genetics contribute 50% to 60% of the risk of developing RA. The genes with the strongest implication include the HLA-DRB1 gene of the major histocompatibility complex (MHC) and chromosome 1's PTPN22 gene. Cigarette smoking increases the production of rheumatoid factor (RF) and anti–cyclic citrullinated peptide antibody (anti-CCP), clinical markers associated with RA, and has been shown to double the risk of developing RA.[5,6] Female sex hormones may also play a role in RA development. In women, peak incidence occurs at the fifth decade, a time when many enter menopause or perimenopause. Estrogen is known to stimulate the immune system; pregnant patients often experience a remission of RA symptoms, and women who take oral contraceptives appear to be somewhat protected against the development of RA.[2,5] Diets rich in fish, olive oil, and other omega-3 fatty acid sources are associated with a lower risk of developing RA.[5]

PATHOPHYSIOLOGY

Pharmacologic therapy for RA targets components of the inflammatory cascade which lead to persistent inflammation of the synovial lining and ultimately cause joint destruction.[7] This normally thin membrane proliferates and transforms into the synovial pannus. The pannus, a highly erosive enzyme-laden inflammatory exudate, invades articular cartilage (leading to narrowing of joint spaces), erodes bone (resulting in osteoporosis), and destroys periarticular structures (ligaments, tendons), resulting in joint deformities (Fig. 44-1).[7,8]

Under normal circumstances, the body can distinguish between self (i.e., proteins found within the body) and nonself (i.e., foreign substances such as bacteria and viruses). On occasion, immune cells (T or B lymphocytes) can react to a self-protein while developing in the thymus or bone marrow. These developing cells are usually killed or inactivated before release from their place of formation; sometimes, however, a self-targeted immune cell can escape destruction and become activated years later to initiate an autoimmune response. Some experts believe the activation of RA is initiated by bacteria (possibly Streptococcus) or a virus containing a protein with an amino acid sequence similar to tissue protein, but this assertion remains disputable.[5] When the activation source (i.e., the self-targeted immune cell) reaches the joint, complex cell–cell interactions take place, leading to the pathology associated with RA.

The initiating interaction for an autoimmune response takes place between antigen-presenting cells (APC), which display complexes of class II MHC molecules, and CD4-lineage T cell lymphocytes (Fig. 44-2). In addition, B cells (previously thought to have little to do with the inflammatory response) can become activated, leading to antibody formation (including RF and anti-CCP), proinflammatory cytokine production, and accumulation of polymorphonuclear leukocytes that release cytotoxins and other substances destructive to the synovium and joint structures. B cells also act as APCs, leading to T cell activation and acceleration of the inflammatory process.[7,8] T cell activation requires two signals: (1) an antigen-specific signal occurring when a class II MHC antigen molecule on an APC binds to a T cell receptor and (2) binding of CD39 on the T cell to either CD80 or CD86 on the APC. T cell activation leads to activation of macrophages and secretion of cytokines, polypeptides that serve as important mediators of inflammation, and cytotoxins, which can directly destroy cells and tissues. Proinflammatory cytokines, such as interleukin (IL) 1 and TNF-α, stimulate both synovial fibroblasts and chondrocytes in neighboring articular cartilage to secrete enzymes that cause degradation of proteoglycan and collagen tissues. In healthy individuals, the inflammatory process is regulated by balancing the ratios of proinflammatory cytokines (e.g., IL-1, IL-6, and TNF-α) with anti-inflammatory cytokines—for example, IL-1 receptor antagonist (IL-1Ra), IL-4, IL-10, and IL-11. In the synovium of patients with RA, however, this balance is heavily weighted toward the proinflammatory cytokines, which results in sustained inflammation and tissue destruction.



Normal
Rheumatoid Arthritis
Normal, thin synovium surrounding joint space
Intact tendons and ligaments
Well-defined joint space
Smooth, intact cartilage surfaces providing protection to bone
Erosion of articular surfaces, leading to bone erosion and osteoporosis
Loosening of tendon sheath and other periarticular structures, leading to joint deformities
Joint space narrowing
Synovial thickening, leading to pannus formation

Figure 44-2 **Schematic representation of events occurring in rheumatoid arthritis.** T cells invading the synovial membrane are primarily CD4+ memory cells, which produce interleukin-2 (IL-2) and interferon-γ (IFN-γ) to a similar extent as antigen-triggered T cells, and which are either already preactivated or become (further) activated by antigen-presenting cells (APCs) in conjunction with arthrogenic (auto)antigen(s) and appropriate major histocompatibility complex (MHC) class II molecules, costimulation (mainly through CD80, CD81, and CD28) and certain cytokines (IL-1, IL-15, IL-18). Through cell–cell contact (e.g., through CD11- and CD69-mediation) and through different cytokines, such as IFN-γ, tumor necrosis factor-α (TNF-α), and IL-17, these T cells activate monocytes, macrophages, and synovial fibroblasts. The latter then overproduce proinflammatory cytokines, mainly TNF-α, IL-1, and IL-6, which seems to constitute the pivotal event leading to chronic inflammation. Through complex signal transduction cascades, these cytokines activate a variety of genes characteristic of inflammatory responses, including genes coding for various cytokines and matrix metalloproteinases (MMPs) involved in tissue degradation. Tumor necrosis factor-α and IL-1 also induce RANK expression on macrophages, which when interfering with RANKL on stromal cells or T cells, differentiate into osteoclasts that resorb and destroy bone. In addition, chondrocytes also become activated, leading to the release of MMPs. Initial events might also involve activation of APCs through Toll-like receptors (TLRs) before T cell engagement. RANK, receptor activator of nuclear factor-κB; RANKL, RANK ligand; RF, rheumatoid factor; TCR, T cell receptor. Reprinted with permission from Smolen JS, Steiner G. Therapeutic strategies for rheumatoid arthritis. Nat Rev Drug Discov. 2003;2:473.

Clinical Presentation, Diagnosis, and Disease Course

CASE 44-1

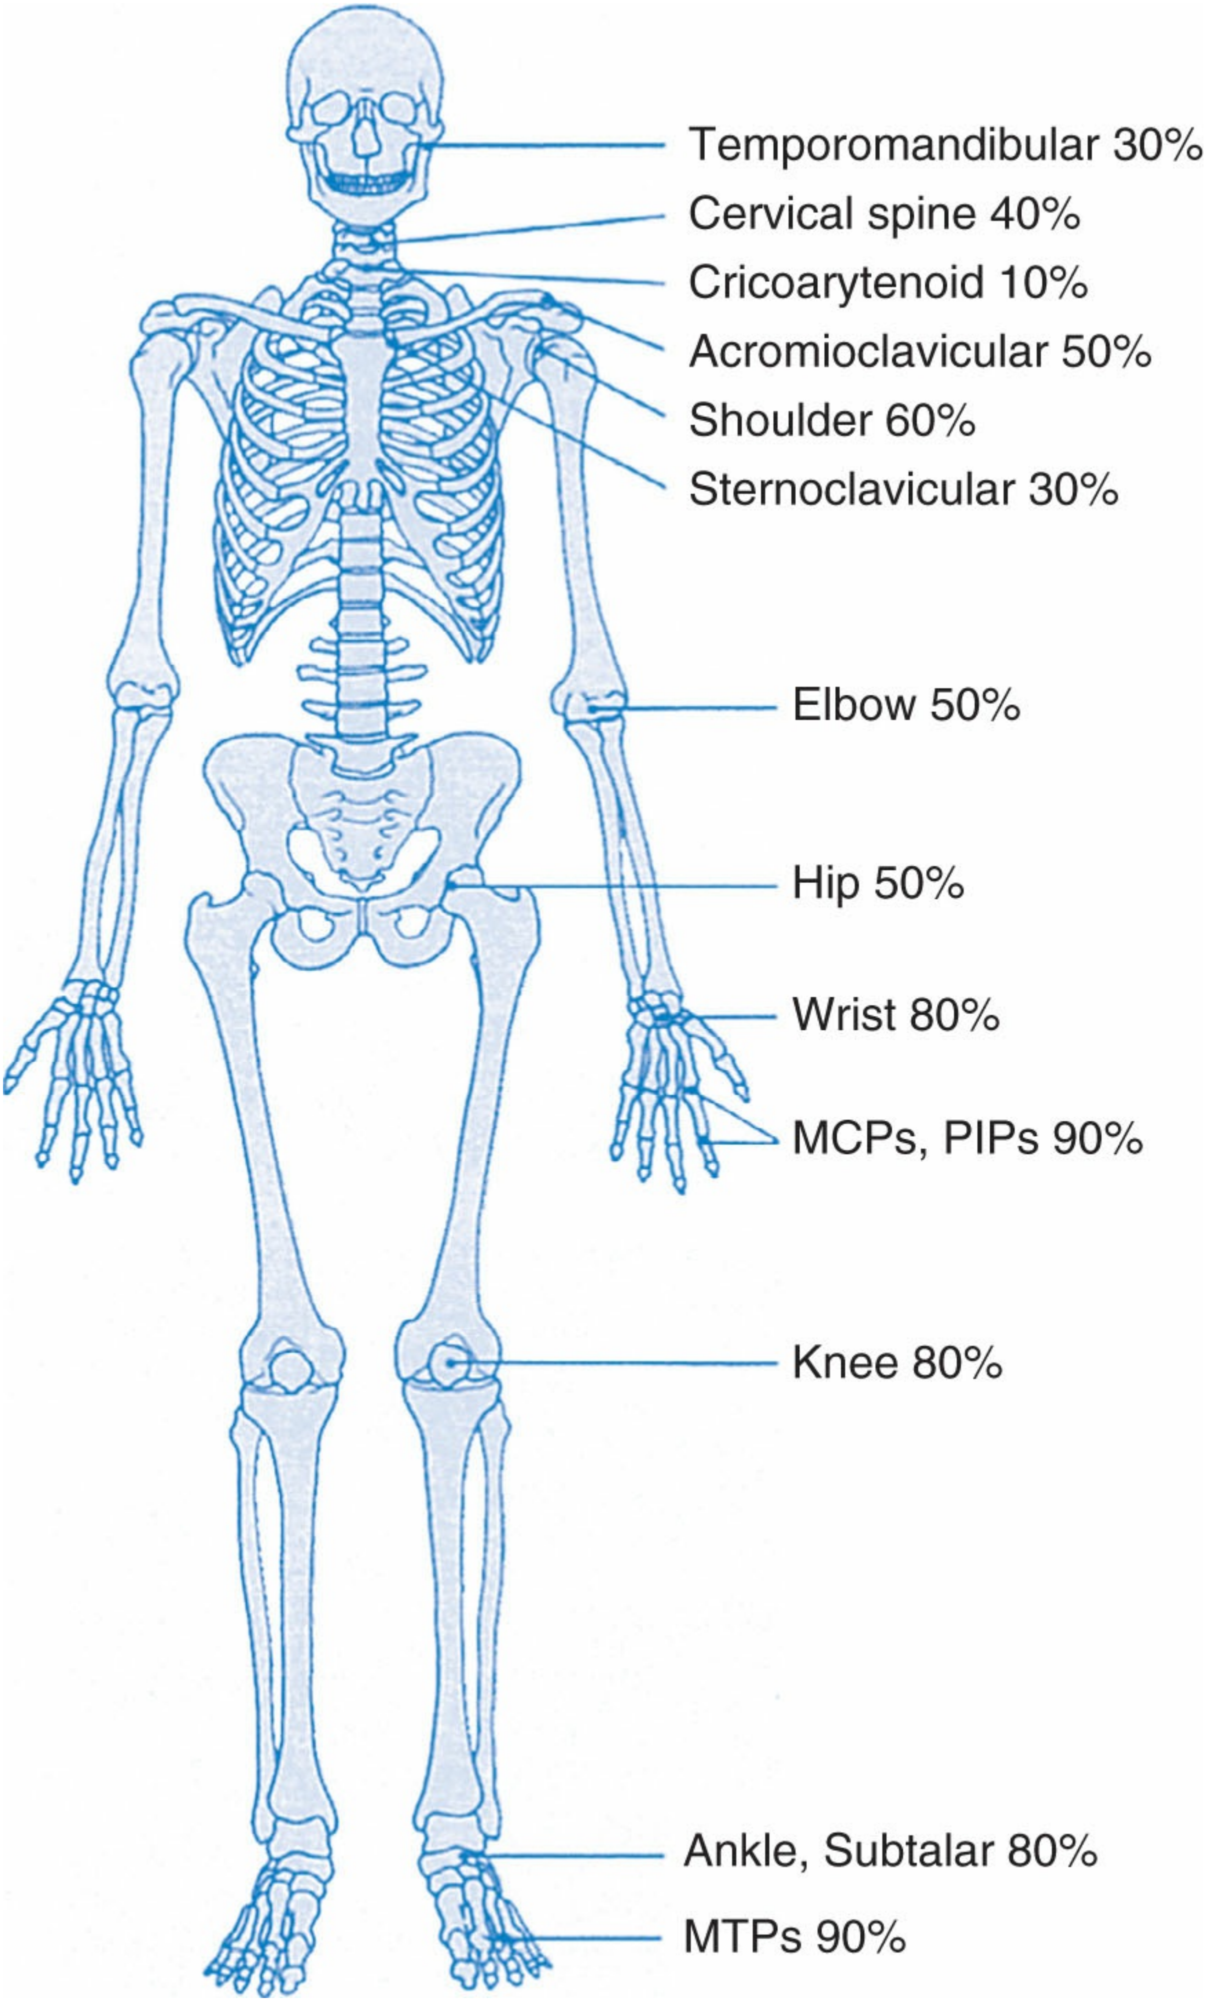
QUESTION 1: T.W., a previously healthy 42-year-old, 60-kg woman, has been suffering from morning stiffness that persists for several hours, fatigue, and generalized muscle and joint pain for the past 4 months. In addition, she reports that her eyes seem red most of the time and are unusually dry. Her symptoms have been much worse during the past month and a half, causing her to limit her physical activities somewhat. She also can no longer wear her wedding ring because of swelling of her hand. Physical examination reveals bilaterally symmetrical swelling, tenderness, and warmth of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and the metatarsophalangeal (MTP) joints of the feet.

Pertinent laboratory findings include the following:

ESR, 52 mm/hour (reference range: males 0 to 15 mm/hour, females 0 to 20 mm/hour)[9]
CRP, 2.1 mg/dL (reference range: 0 to 0.5 mg/dL)
Hemoglobin, 10.6 g/dL
Hematocrit, 33%
Platelets, 480,000/μL
Albumin, 3.8 g/dL
Serum iron, 40 mcg/dL
Total iron-binding capacity, 275 mg/dL
Positive anti-CCP at 82 units (reference range: <20 units/mL)
Positive RF performed by latex fixation method in a dilution of 1:320 (reference range: <1:80)

Tests for antinuclear antibodies (ANA) and tuberculin sensitivity are negative. Her uric acid level is normal. Radiographic films of the hands and feet show soft tissue swelling, narrowing of joint spaces, and marginal erosions of the second and third MCP and PIP joints bilaterally with no evidence of calcification. Other routine laboratory data and physical findings are normal. What signs and symptoms of RA are manifested by T.W.?

More than 50% of RA cases, like that seen in T.W., will have slow onset of symptoms over weeks to months, although up to 15% of patients experience acute-onset RA, with rapid development of symptoms over several days. Onset of symptoms may be either articular or systemic, including nonspecific complaints such as fatigue, weakness, muscle pains, weight loss, and low-grade fever. Joint involvement is characterized by soft tissue swelling and warmth, decreased range-of-motion (ROM), and sometimes muscle atrophy around affected joints. Most common complaints include pain and stiffness in multiple joints. Classically, as illustrated by T.W., presentation is symmetrical involving wrists, proximal interphalangeal joints, and metacarpophalangeal joints, although asymmetrical joint involvement also occurs with symmetry developing later in the disease course. The peripheral joints of the hands, wrists, and feet are usually involved first. Reflective of joint inflammation, patients usually experience prolonged morning stiffness on awakening lasting at least 30 to 45 minutes, but it can be present all day with decreasing intensity after arising.[10,11] Morning stiffness lasting for more than 1 hour rarely occurs in other diseases outside of RA.[12]



Temporomandibular 30%
Cervical spine 40%
Cricoarytenoid 10%
Acromioclavicular 50%
Shoulder 60%
Sternoclavicular 30%
Elbow 50%
Hip 50%
Wrist 80%
MCPs, PIPs 90%
Knee 80%
Ankle, Subtalar 80%
MTPs 90%

Figure 44-3 Frequency of involvement of different joint sites in established rheumatoid arthritis. MCPs, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; PIPs, proximal interphalangeal joints.

Ultimately, any or all of the diarthrodial joints (elbows, knees, shoulders, ankles, hips, temporomandibular joints, sternoclavicular joints, and glenohumeral joints) can be involved (Fig. 44-3). Progressive disease is characterized by irreversible joint deformities, such as ulnar deviation of the fingers (Fig. 44-4), boutonniere deformities (hyperextension of the DIP joint and flexion of the PIP joint), or swan neck deformities (hyperextension of the PIP joint and flexion of the DIP joint) (Fig. 44-5). Similar irreversible deformities can also involve the feet. Patients with more aggressive disease (multiple joint involvement, positive RF) have a greater than 70% probability of developing joint damage or erosions within 2 years of disease onset.[13]

CASE 44-1, QUESTION 2: Which laboratory values in T.W. could be used to monitor her RA disease progression?

Physical assessment of an RA patient is fundamental to monitoring and evaluating patient course. For instructions on how to perform a basic musculoskeletal examination, go to http://meded.ucsd.edu/clinicalmed/joints.htm and scroll to select either knee, shoulder, hand, hip, or lower back examinations.

In 2010, the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) developed new classification criteria for RA. In comparison to criteria previously outlined in 1987, the intent of the new classification was to identify patients early in disease development so that therapeutic intervention can be initiated as soon as possible, ultimately decreasing disease progression and improving clinical outcomes.[14]

Because no single chemical or laboratory finding is specific for the disease, the diagnosis of RA is based on multiple clinical criteria (Table 44-1). Individuals presenting with clinical synovitis (swelling) not explained by other differential diagnoses such as systemic lupus erythematosus, psoriatic arthritis, or gout, among others, should be tested for RA. RA criteria in the new classification system include quantifying joint involvement and symptom duration as well as detecting presence of autoantibodies and acute-phase reactants.[11,14–16] Using a score-based algorithm based on these four categories, a summative score of 6 or more out of a total possible score of 10, as seen in T.W., suggests RA.[14]

Individually, each of the laboratory findings is characteristic for chronic systemic inflammatory disease with no test being specific for RA, although rheumatoid factor (RF) and anti–citrullinated peptide (anti-CCP) are more definitive than erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP).[9] Specifically, autoimmune diseases are frequently characterized by autoantibodies, with 50% to 80% of RA individuals having RF, anti-CCP, or both.[11,15,16]

RF, an IgM or IgG autoantibody, abnormally reacts with the Fc portion of IgG to form an immune complex. It is found in 75% to 80% of patients with RA. It may also present in up to 5% of healthy individuals and in patients with diseases other than RA, including almost any condition associated with either immune complex formation or with hypergammaglobulinemia (e.g., chronic infections, lymphoproliferative and hepatic diseases, systemic lupus erythmatosus, and Sjogren's syndrome). An RF titer of at least 1:160 is considered a positive test and most patients with RA, such as T.W., typically have titers of at least 1:320.[9,17] Overall, RF is neither sensitive nor specific enough to independently diagnose RA, but it is found in the majority of patients and a higher titer early in disease generally correlates with increased disease severity and progression.[18]

Table 44-1

Criteria for Diagnosis of Rheumatoid Arthritis

Criteria	Score[a]
Joint Involvement	
1 large joint[b]	0
2–10 large joints	1
1–3 small joints[c]	2
4–10 small joints	3
>10 small joints	5
Serology[d] (≥1 result needed)	
Negative RF and negative anti-CCP	0
Low-positive RF or low-positive anti-CCP	2
High-positive RF or high-positive anti-CCP	3
Acute-Phase Reactants	

Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms	
<6 weeks	0
≥6 weeks	1

[a] Score-based algorithm: add score of all categories; score of ≥6/10 needed to classify patient as having definite RA.

[b] Shoulders, elbows, hips, knees, and ankles.

[c] metacarpophalangeal, proximal interphalangeal, second through fifth metatarsophalangeal, thumb interphalangeal joints and wrists.

[d] negative, IU ≤ upper limit of normal (ULN); low-positive, IU higher than ULN but ≤3 times ULN; high-positive, >3 times ULN; if RF assay only available as positive or negative, positive RF interpreted as low-positive.

Source: Aletaha D et al. 2010 rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative [published correction appears in Ann Rheum Dis. 2010;69:1892]. Ann Rheum Dis. 2010;69:1580.

anti-CCP, anti–cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RA, rheumatoid arthritis; RF, rheumatoid factor.

Citrulline, a nonstandard amino acid, is also established as a key component of RA antigenicity and is more specific for RA than RF. Citrullinated proteins and anti-CCP antibodies are abundant in inflamed RA synovium. Anti-CCP antibodies can be detected in 50% to 60% of early RA patients, and the specificity of anti-CCP is very high at 90% to 95%.[9] Anti-CCP is present as early as 1.5 to 9 years before symptom presentation, suggesting a pathogenic role for these antibodies in RA.[19,20] A positive anti-CCP also correlates with an increased likelihood of a more erosive course of RA than either a negative anti-CCP or a positive RF. In summary, a positive anti-CCP antibody test is highly specific for RA, predictive of the development of RA, is a marker for an erosive disease course, and in combination with positive RF also correlates with 99.5% specificity for RA, making the likelihood of T.W. not having RA very minimal.[9,21]

The nonspecific markers for inflammation include ESR and CRP, but unfortunately these acute-phase responses are also not disease-specific. T.W.’s hematologic findings are consistent with a mild anemia of chronic inflammation. Although her serum iron concentration is decreased, her normal iron-binding capacity makes a diagnosis of iron-deficiency anemia unlikely. Her anemia probably results from a failure of iron release from the reticuloendothelial tissues and would not be expected to respond to iron therapy. The mild thrombocytosis is additional evidence of a systemic inflammatory response. The laboratory manifestations of inflammation should improve with effective drug therapy and, along with many of the clinical features of RA, are useful parameters for monitoring disease activity and response to therapy.

Finally, the test for ANA rules out systemic lupus erythematosus in T.W. The ANA, however, can be positive in 10% to 70% patients with RA.[14]

EXTRA-ARTICULAR MANIFESTATIONS AND COMPLICATIONS

The classic RA presentation involves joint findings; however, RA is a systemic disease reflected by accompanying extra-articular and organ system manifestations that, chronically, can occur in up to 46% of patients. These manifestations are also associated with higher disease activity,[22] and those with systemic involvement have higher mortality rates than those without, suggesting that early treatment may lower both the risk and severity of RA complications.[22,23]

Rheumatoid nodules occur in 15% to 20% of patients and are typically found on extensor surfaces, pressure points, and tendons. Pleuropulmonary manifestations include pulmonary nodules, fibrosis, and pleuritis; interstitial pneumonitis and arteritis of the pulmonary vasculature, although rare, can be potentially life-threatening. Vasculitis occurs infrequently, is more common in patients with long-standing and often severe disease. Complications include skin ulceration, peripheral neuropathy, and arteritis of organs.[10]

Some extra-articular manifestations occur as syndromes. Sjögren syndrome includes dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia), and connective tissue disease. T.W.'s eye complaints may be an extra-articular manifestation of her RA. Felty syndrome is characterized by chronic arthritis, splenomegaly, and neutropenia; thrombocytopenia, anemia, and lymphadenopathy may also be present.[10]

Individuals with RA have a median life expectancy that is 3 to 10 years shorter than non-RA populations, with lower life expectancy associated with more severe disease.[5,24] The excess mortality has been attributed primarily to accelerated cardiovascular disease, responsible for one-third to one-half of deaths among adults compared with one-fourth to one-fifth of deaths among adults without RA. RA is associated with a twofold to threefold increased rate of myocardial infarction (MI), as well as lower MI survival. Management of cardiovascular risk include annual cardiovascular risk evaluations for all patients, multiplying risk scores by 1.5 for patients with more than one marker of severe disease activity, use of statins and cardiovascular medications known to reduce cardiovascular risk, caution when prescribing nonsteroidal anti-inflammatory drugs (NSAIDs) owing to associated cardiovascular risk, and smoking cessation (Table 44-2).[25] Finally, pericarditis and myocarditis, while rare, may also occur.

Table 44-2

Recommendations for Reducing Cardiovascular Risk[a] in Patients with Rheumatoid Arthritis (Evidence/Strength Rating)[b]

1. Rheumatoid arthritis should be considered as a disease in which cardiovascular risk is elevated, because of both an increased prevalence of traditional cardiovascular risk factors and the inflammatory burden. Although the evidence base is less, this may also apply to ankylosing spondylitis and psoriatic arthritis (2b–3/B).
2. To lower cardiovascular risk, adequate control of arthritis disease activity is necessary (2b–3/B).
3. All patients with rheumatoid arthritis should undergo annual cardiovascular risk evaluation with use of national guidelines. This should also be considered for all patients with ankylosing spondylitis and psoriatic arthritis. When antirheumatic treatment has been changed, risk assessments should be repeated (3–4/C).
4. For patients with rheumatoid arthritis, risk score models should be adapted by introducing a 1.5 multiplication factor when the patient meets two of the following three criteria: disease duration of more than 10 years, rheumatoid factor or anti–cyclic citrullinated peptide positivity, and the presence of certain extra-articular manifestations (3–4/C).
5. When using the Systematic Coronary Risk Evaluation model for determination of cardiovascular risk, triglyceride to high-density lipoprotein cholesterol ratio should be used (3/C).
6. Intervention for cardiovascular risk factor management should be performed according to national guidelines (3/C).
7. Preferred treatment options are statins, angiotensin-converting enzyme inhibitors, or angiotensin II blockers (2a–3/C–D).
8. The effect of cyclo-oxygenase-2 inhibitors and most nonsteroidal anti-inflammatory drugs on cardiovascular risk is not completely determined and should be studied further. Clinicians should therefore be very cautious in prescribing these drugs, especially to patients with cardiovascular risk factors or with documented cardiovascular disease (2a–3/C).
9. When corticosteroids are prescribed, this should be at the lowest possible dose (3/C).
10. Patients should be actively encouraged to stop smoking (3/C).

[a] Cardioprotective treatment is recommended when 10-year cardiovascular risk is above the threshold of “moderate” that is established for each country (i.e., either 10% or 20%).

[b] Level of Evidence: Category 1A, from meta-analysis of randomized, controlled trials; 1B, from at least one randomized, controlled trial; 2A, from at least one controlled study without randomization; 2B, from at least one type of quasi-experimental study; 3, from descriptive studies, such as comparative studies, correlation studies, or case-control studies; 4, from expert committee reports or opinions or from clinical experience of respected authorities; Strength of recommendation directly based on A, category 1 evidence; B, category 2 evidence or extrapolated recommendations from category 1 evidence; C, category 3 evidence or extrapolated recommendations from category 1 or 2 evidence; D, category 4 evidence or extrapolated recommendations from category 2 or 3 evidence.

Treatment

The treatment goals of RA are to maximize functional status through maintenance or improvement of symptoms (e.g., joint pain and swelling), preserve joint function, and prevent deformity to ultimately improve quality of life and delay disability. Treatment to achieve remission or lowest possible disease activity involves a combination of interventions. Early initiation of pharmacologic therapy starting at the point of diagnosis is critical to quality RA care.[26–28] Other supportive interventions include rest, exercise and physical therapy, occupational therapy, and emotional support.

CASE 44-1, QUESTION 3: What nonpharmacologic therapy should be included in the management of T.W.'s RA?

Systemic and articular rest (achieved by splinting the affected joints) can reduce inflammation significantly. Restful and adequate sleep are particularly important in chronic, fatigue-inducing diseases such as RA. Therefore, T.W. should rest often especially when experiencing acute inflammation, but daytime rest periods should be limited to 30 to 60 minutes each as prolonged rest can also induce rapid losses in strength and endurance. Splinting of joints is typically prescribed throughout the day and night during periods of active inflammation, then only at night for several weeks after cessation of inflammation.[29]

Passive ROM exercises should be prescribed for T.W. because they minimize muscle atrophy and flexion contractures and maintain joint function without increasing inflammation or radiographic progression of disease.[29,30] Regular aerobic exercises, such as cycling, swimming, or walking, enhance muscle function and joint function as well.[31] Overall, physical and occupational therapies can provide valuable assistance to patients with compromised activities of daily living to maximize the potential for self-sufficiency. Some orthoses—medical devices secured to any part of a patient's body designed to support, immobilize, align, correct, or prevent deformity, or improve functioning—can reduce pain and inflammation or improve joint function in targeted joints for RA patients.[32]

Finally, emotional support should be provided to all patients including T.W. As with all chronic debilitating diseases, the potential loss of independence, self-esteem, and employment, as well as altered interpersonal relationships with friends and family, can result in a twofold to threefold increase in depression.[33,34]

The expertise of different health care disciplines (e.g., physical therapists, social workers, health educators, psychiatrists, clinical psychologists, podiatrists, vocational rehabilitation therapists, and pharmacists) should be consulted depending on T.W.'s needs. Pharmacists in outpatient clinical practices can monitor RA drug therapy for therapeutic and adverse effects under collaborative practice agreements with other practitioners and can counsel patients on proper medication use and clarify expectations.[35]

Insufficient literature evidence is available to support the use of spa therapy and thermotherapies such as ultrasound, electrotherapies (e.g., transcutaneous nerve stimulation and electrostimulation of muscles), and laser therapy in the treatment of

RA. Heat treatments in general should be avoided during periods of active joint inflammation because heat can further exacerbate pain and swelling.[36]

While symptoms of RA may be controlled by conservative management, more aggressive therapy is needed to prevent disease progression and disability. Nonsteroidal anti-inflammatory drugs (NSAIDs) are often used to provide rapid anti-inflammatory and analgesic effects. However, they do not prevent or slow joint destruction as compared to the disease-modifying antirheumatic drugs (DMARDs) and should be reserved for rapid symptomatic relief while awaiting DMARD onset of action. DMARDs do alter long-term disease course. As such they are the mainstay of pharmacologic care and should be initiated in all patients as soon as they are diagnosed with RA.[26–28] Specific choice of treatment is individualized based on joint function, degree of disease activity, patient age, sex, occupation, family responsibilities, drug costs, and results of previous therapy. The two classes of DMARDs are synthetic chemical compounds (sDMARDs) and biologic agents (bDMARDs). With the recent advent of tofacitinib, EULAR has further subdivided sDMARDs into the conventional sDMARDs (csDMARDs) and targeted sDMARD (tsDMARD).[26,27]

csDMARDs (e.g., hydroxychloroquine [HCQ], sulfasalazine [SSZ], methotrexate [MTX], and leflunomide [LEF]) have demonstrated the ability to slow disease progression. These agents, alone or in combination, are considered as initial therapy for most patients and in the absence of contraindication, MTX is the treatment of choice because of its strong efficacy and favorable safety profile. Other csDMARDs such as azathioprine [AZA], gold, and D-penicillamine are rarely used because of slow onset of action and toxicity profile.[26,27] The first and only tsDMARD, tofacitinib, is considered in those with moderate-to-severe disease who have failed treatment with or are intolerant to methotrexate.[37]

The bDMARDs, also referred to as anticytokines, biologics, biologic modifiers, or biologic response modifiers, target the physiologic proinflammatory and joint-damaging effects of inflammatory mediators, including TNF-α, IL-1, IL-6, T cell, and B cells. Agents in this class include the TNF-α inhibitors (adalimumab [ADA], certolizumab pegol [CZP], etanercept [ETA], golimumab [GLM], and infliximab [IFX]), anti-IL-1 receptor antagonist (anakinra), anti-B cell therapy (rituximab [RXB]), IL-6 receptor antagonist (tocilizumab [TCZ]), and the T cell modulator (abatacept [ABT]). The bDMARDs are typically reserved for patients who fail to achieve an adequate response with csDMARD monotherapy.[28]

Corticosteroids are also potent anti-inflammatory agents that slow the progression of joint damage in RA. However, long-term systemic use should be avoided because of serious adverse effects associated with chronic therapy. Short-term oral therapy may be reserved as bridge therapy in early RA with moderate-to-high disease activity while awaiting onset of DMARD activity, brief periods of active disease, or with therapy failure.[28] Local intra-articular injections may be used for isolated joints experiencing disease flares.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs have a long history of use in RA treatment. They are effective for providing short-term pain and inflammation control but do not alter disease course.[38] In addition, NSAIDs are associated with side effects related to COX inhibition such as GI intolerance, nephrotoxicity, and increased risk of bleeding and cardiovascular events. The cardiovascular risk associated with some agents is particularly concerning since RA patients are at higher cardiovascular mortality risk. Therefore, given both the safety profile and the lack of long-term disease-modifying efficacy, NSAID use should be judicious and reserved only as an adjunct to DMARD therapy.[38,39]

Although NSAIDs differ in chemical structure, they generally have similar pharmacologic properties (e.g., antipyresis, analgesia, anti-inflammatory activity, and inhibition of prostaglandin synthesis), mechanisms of action (i.e., inhibition of COX activity), pharmacokinetic properties (e.g., highly protein bound and extensively metabolized to renally cleared inactive metabolites), and side effect profile.[40] Aspirin, an acetylated salicylate, is the standard against which the effectiveness of all other NSAIDs are measured. Other NSAIDs are available, including nonacetylated salicylates (e.g., salsalate, choline salicylate, and magnesium salicylate) and nonsalicylate or nonaspirin NSAIDs (e.g., ibuprofen, naproxen, and cyclo-oxygenase [COX] inhibitors). (Note: For simplicity and clarity, the term NSAID is used henceforth to describe NSAIDs other than acetylated [i.e., aspirin] and nonacetylated salicylates.)[38–40] Choice of particular NSAID has traditionally been based on cost, duration of action, and patient preference because of interpatient variability in response. Courses of several different NSAIDs, even those within the same chemical class, may be necessary to determine the best choice for an individual patient.

CONVENTIONAL SYNTHETIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (csDMARDs)

With rare exception, every patient should receive csDMARD therapy soon after diagnosis to minimize loss of joint integrity, function, and risk of cardiovascular disease related to RA.[26,28] Although csDMARDs have the potential to cause serious toxicity, they can substantially reduce joint inflammation, reduce or prevent joint damage, maintain joint function and integrity, and ultimately reduce health care costs and allow patients to remain productive.[26,27] The onset of action of most csDMARDs is slow over 3 to 6 months; however, SSZ, MTX, and LEF can be beneficial within 1 to 2 months.[38] Several factors must be considered when selecting a csDMARD, including convenience of administration, monitoring requirements, medication and monitoring costs, time to therapeutic onset, and frequency and severity of adverse reactions.

MTX, a folate antimetabolite with immunosuppressive and anti-inflammatory properties, remains the mainstay first-line DMARD because of its relatively rapid onset of action and excellent history of efficacy and safety.[26,28] LEF and SSZ are recommended if a contraindication to MTX is present, or if intolerance to MTX occurs. The primary metabolite of LEF, A77 1726 (M1), is responsible for nearly all of its pharmacologic activity. Although the exact mechanism of M1 is not completely understood, it is known that M1 inhibits dihydro-orotate dehydrogenase, an enzyme in cell mitochondria responsible for catalyzing an important step in de novo pyrimidine synthesis; this is believed to be its main mechanism of action. SSZ appears to induce anti-inflammatory effects through one of its active metabolites, mesalamine, which is believed to inhibit both COX and lipooxygenase. HCQ as monotherapy or in combination may be used for relatively mild cases of RA.[26] The mechanism of anti-inflammatory effect of HCQ may be attributable to inhibition of migration of neutrophils and eosinophils, histamine and serotonin blockade, or inhibition of prostaglandin synthesis. Older csDMARDs such as azathioprine, cyclosporine, minocycline, and gold are no longer recommended because of the superior risk–benefit ratio of other csDMARDs, bDMARDs, and tofacitinib.[28]

TARGETED SYNTHETIC DMARD (tsDMARD)

Tofacitinib was recently placed in its own medication subcategory by ACR and EULAR since the janus kinase (JAK) inhibitor, a targeted molecule involved with inhibition of signal transduction pathways, is mechanistically different from the csDMARDs. Tofacitinib inhibits JAKs, enzymes that stimulate inflammatory cytokines; therefore, inhibition modulates leukocyte function and immune response. It is indicated for individuals with moderate-to-high disease activity who have failed csDMARD monotherapy.[26,28]

BIOLOGIC DMARDs (bDMARDs)

In general, the bDMARDs are reserved for patients who have failed to respond to one or more csDMARDs alone or in combination. The ACR and EULAR guidelines recommend the use of bDMARDs in patients with established RA who experience moderate or high disease activity despite csDMARD monotherapy.[26,28] The ACR guidelines also recommend the use of bDMARDs in early RA (<6 months) in patients with moderate-to-high disease activity despite csDMARD monotherapy.[28] Since the late 1990s a total of nine biologic agents have been approved for RA treatment. The earliest biologic agents targeted proinflammatory cytokines, such as TNF-α and IL-1, which play key roles in the immunopathogenesis of RA.[41] These cytokines are abundant in rheumatoid synovial tissues and fluid. Most cytokines can independently induce expression of the others, and IL-1 is capable of upregulating its own expression.[42] Excessive macrophage-produced cytokines (e.g., TNF-α, IL-1, IL-6, and IL-8) correlate closely with RA disease activity and severity. Most importantly, RA improves when the physiologic action of TNF-α or several different ILs are suppressed. In more recent years, new agents have been developed to target additional key processes in RA, including T cell costimulation, the depletion of CD20+ B cells, and the inhibition of IL-6.[39]

The proinflammatory cytokine TNF-α is produced by activated macrophages and T cells in RA-affected joints. It also plays a role in keeping infections localized by increasing platelet activation and adhesion, resulting in local blood vessel occlusion and containment of infection. This action of TNF-α is responsible for its tumor necrosis properties, thus leading to the name. TNF-α exerts its physiologic effects by binding to two different cell-surface receptors known as p55 (i.e., 55 kDa) and p75 (i.e., 75 kDa) on inflammatory cells.[41] These receptors, with portions extending from within the cell cytoplasm to the cell exterior, are capable of binding TNF-α to the domains extending above the cell surface. Soluble forms of these receptors can be found in the serum and synovial fluid and seem to play a role in regulating TNF-α.

Two approaches have targeted the action of TNF-α: (1) the use of soluble TNF receptors with high TNF-binding affinity (i.e., etanercept) and (2) antibodies against TNF-α (i.e., infliximab, adalimumab, golimumab, and certolizumab pegol).[39] Etanercept is a recombinant TNF-receptor Fc fusion protein with the extracellular portion of two p75 receptors fused to the Fc portion of human immunoglobulin G1 (IgG1).[43,44] Infliximab is a chimeric IgG monoclonal antibody directed against TNF-α, and adalimumab is a genetically engineered human IgG1 monoclonal antibody.[45,46] Certolizumab pegol is a polyethylene glycolated (PEG) Fab fragment of a humanized anti-TNF monoclonal antibody. Golimumab is a fully human anti-TNF-α IgG1 monoclonal antibody that targets and neutralizes both soluble and membrane-bound forms of TNF-α.[48,49] All five TNF-α inhibitors render TNF biologically unavailable and are highly effective in reducing RA disease activity. Currently, there is no conclusive evidence from well-controlled comparative trials that any one TNF-α inhibitor is superior to another with regard to efficacy and safety.[50] Comparative efficacy and safety will be discussed further in the section “Pharmacologic Treatment.” TNF-α inhibitor selection may be driven by cost, insurance coverage, provider preference, and patient-specific factors.

There are also three non-TNF biologic agents recommended for RA patients who have not responded to at least one csDMARD, which include abatacept, rituximab, and tocilizumab.[28] Each of these agents possesses a novel mechanism of action targeting either T cells, B cells, or IL-6. Abatacept and tocilizumab may be considered as first-line biologic DMARDs along with the TNF-α inhibitors. However, rituximab should only be considered as a first-line bDMARD in the presence of certain contraindications (i.e., recent history of lymphoma, latent TB with contraindications to treatment, or history of demyelinating disease) to the other bDMARDs.[26] There is also one final bDMARD, anakinra, which is seldom used because of lack of comparative efficacy. Anakinra is a recombinant human interleukin-1 (IL-1) receptor antagonist, which inhibits the binding of cytokines IL-1a and IL-1b to their receptor.[39] In healthy individuals, IL-1 overexpression is prevented by naturally occurring IL-1Ra.[41,51] Consequently, inadequate production of IL-1Ra, relative to IL-1, is hypothesized to be an important contributor to active RA. In addition to proinflammatory properties, IL-1 augments cartilage damage and inhibits bone formation. Anakinra has not shown comparable efficacy against other bDMARDs in meta-analyses and is infrequently used, although some individuals may still respond to this agent.[26,27] Anakinra was not included in the most recent ACR 2015 guidelines owing to lack of any new data since 2012 and infrequent use in RA.[28]

Abatacept is a selective costimulation modulator that inhibits T cell activation.[52] For T cells to be fully activated, a CD80/CD86:CD28 costimulatory signal is required.[53] This costimulation is blocked by cytotoxic T-lymphocyte–associated antigen 4. Abatacept, a soluble fusion protein consisting of extracellular cytotoxic T-lymphocyte–associated antigen 4 attached to the Fc portion of IgG1, which inhibits T cell activation by preventing the binding of CD80 and CD86 ligands on the surface of APCs to the CD28 receptor on the T cell.[53]

Rituximab, is a chimeric monoclonal antibody, binds to the CD20 antigen on the surface of pre-B cells and mature B cells, resulting in the depletion of B cells from peripheral blood, lymph nodes, and bone marrow.[54] Stem cells, pro-B cells, and antibody-producing plasma cells do not express CD20 and are not affected by RXB. The exact role of B cells in RA pathogenesis is not known. However, studies have shown that B cells may contribute to the autoimmune and inflammatory processes by producing RF, acting as APCs, activating T cells, and producing proinflammatory cytokines.[54] Owing to its chimeric composition, RXB must be administered with MTX to reduce the risk of human antichimeric antibody (HACA) formation.[55,56] Inhibition of T cell activation and depletion of proinflammatory B cells result in significant reductions in RA-related inflammation and joint destruction.

Tocilizumab is a humanized anti–IL-6 receptor antibody. The pleiotropic proinflammatory cytokine IL-6 is produced by a variety of cell types including lymphocytes, monocytes, and fibroblasts and is involved in multiple immunologic processes, including T cell activation and B-cell proliferation.[57] When bound to the soluble IL-6 receptor, IL-6 activates chemokine production and upregulates expression of adhesion molecules. This leads to the recruitment of leukocytes at inflammatory sites, thus implicating IL-6 as an important factor in RA.[58,59] High levels of IL-6 have been found in the serum and joints of patients with RA. Additionally, IL-6 has been shown to induce proliferation of osteoclasts, which may be a component of the bone degradation seen in RA.[58,59] TCZ is a humanized, monoclonal antibody that can bind to both membranous and soluble IL-6 receptors.

This blockade prevents the interaction of IL-6 with the IL-6 receptor, thus interrupting the inflammatory pathways that contribute to the disease processes in RA.[58,59]

Owing to their immunosuppressive nature, all bDMARDs should be avoided in patients with serious infections until the infection has been controlled. All five of the TNF-α inhibitors as well as tocilizumab carry boxed warnings for serious infections. Although these infections occurred primarily among patients with significant risk factors for infection (e.g., poorly controlled diabetes, concurrent corticosteroid use, or concomitant csDMARD therapy), biologic agents should not be given to patients with active infection, history of recurring infections, or medical conditions predisposing them to infection. There has been some debate regarding whether or not bDMARDs are associated with an increased risk of serious infections when compared to csDMARDs. A recent meta-analysis including all currently available bDMARDs concluded that standard and high-dose biologic DMARDs are associated with an increase in risk of serious infections compared to csDMARDs. Risk was increased whether or not the patient was using csDMARDs concomitantly. However, low-dose bDMARDs were not associated with increased risk.[60] It is recommended that all patients be screened for latent tuberculosis infection (LTBI) prior to initiation of a bDMARD or tofacitinib. If LTBI is identified, patients should receive at least 1 month of treatment prior to starting a bDMARD or tofacitinib. Patients with active TB should complete treatment prior to initiation of a bDMARD or tofacitinib. Patients should be monitored for active TB during treatment.[28]

It is recommended that patients receive the following vaccinations prior to the initiation of csDMARD or bDMARD therapy: pneumococcal, influenza, hepatitis B, human papillomavirus, and herpes zoster. However, if not completed prior to the initiation of therapy, these vaccinations, with the exception of herpes zoster, may be given following the initiation of csDMARDs or bDMARDs. Herpes zoster, as well as any other live vaccines, should not be administered in patients receiving bDMARDs.[28]

CORTICOSTEROIDS

Corticosteroids (i.e., low oral doses for multiple joint involvement or injections into isolated joints) can be used as needed at disease onset while awaiting response to DMARD therapy and intermittently during disease flare-ups or following failure of optimized treatment to control symptoms of pain and swelling. Corticosteroids have a long history of use in RA because of their potent anti-inflammatory and immunosuppressive effects and have been shown to enhance the clinical, functional, and structural efficacy of baseline csDMARD or combination csDMARD and bDMARD therapies.[26] Corticosteroids administered orally at low dosages or through local injections are effective in rapidly reducing disease activity and relieving RA symptoms.

Corticosteroids are particularly beneficial when patients are awaiting the onset of

DMARD action (known as “bridge therapy”) or during flares of active RA involving a small number of joints.[28,61] Oral corticosteroids seem to slow the rate of disease progression and have been shown to reduce radiographic changes for 1 to 2 years.[36,61,62] Use of corticosteroids in combination with DMARD therapy appears to improve clinical outcomes (signs and symptoms, functionality, radiologic damage) for patients with RA above the benefit of a DMARD used alone.[36,61,62] In addition, newer modified-release corticosteroids targeting nocturnal increases in inflammatory mediators, IL-6 and cortisol, have demonstrated a reduction in morning stiffness compared with older, standard immediate release agents.[63–65] Long-term use of corticosteroids, however, is associated with many serious adverse effects (e.g., osteoporosis, weight gain, diabetes, cataract formation, adrenal suppression, hypertension, infections, and impaired wound healing).[66] As a result, oral corticosteroid dosing should be limited to daily doses of ≤10 mg of prednisone (or equivalent) and should be administered for as short a time as possible.[28] Frequent corticosteroid injections for an extended period have the potential to accelerate bone and cartilage deterioration; therefore, the same joint should not be injected more than once every 3 months.[66]

SELDOM-USED DISEASE MODIFYING ANTIRHEUMATIC DRUGS AND OTHER THERAPIES

Several DMARDs, including gold, azathioprine, cyclosporine, minocycline, and anakinra, are no longer included in EULAR and ACR treatment recommendations because of infrequent use and lack of any new data supporting clinical benefit, especially

---

in light of other widely available agents with more favorable benefit-to-risk profiles.[26–28]

Two classes of NSAIDs in development may provide GI protection without COX-2 specificity. The first class, nitric oxide NSAIDs, also known as COX-inhibiting nitric oxide donors, are standard NSAIDs structurally linked to a nitric oxide moiety. By donating nitric oxide to the gastric mucosa, nitric oxide NSAIDs produce the same gastroprotective effect as prostaglandins and have a lower rate of gastrointestinal ulceration compared to classic agents.[67] The other class, so-called dual-inhibitor NSAIDs, blocks both enzymatic pathways of arachidonic acid metabolism (i.e., both COX and 5-lipoxygenase) and further broadens the pharmacologic effects of currently available NSAIDs. Although COX inhibition is clearly associated with GI toxicity, inhibition of both enzymatic pathways of arachidonic acid metabolism has been GI sparing in animal and initial human safety studies.[68,69]

RA vaccines are also in development.[70] Only phase II studies have been completed, but a recent trial demonstrated clinical improvement in the majority of RA patients receiving T cell immunotherapy.[71] This RA vaccine induces a specific immune response against T cells that are reactive to joint antigens.[70] Another trial using immune-modulatory therapy targeted toward anti-CCP autoantibodies also demonstrated clinical improvement in patients with active RA.[72]

CLINICAL USE OF DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Both ACR[27,28] (Fig. 44-6) and EULAR[27] have developed evidence-based recommendations for the use of DMARDs in RA, last updated in 2015 and 2013, respectively. The two sets of guidelines have more similarities than differences. Ultimately, choice of treatment modality will be based on efficacy and safety data as well as on patient-specific parameters.

DMARD treatment should be started as soon as possible following RA diagnosis. MTX remains the gold standard because of high response rate, mild side effect profile, low cost, and long sustained efficacy not just as monotherapy but also in combination with glucocorticoids, other csDMARDs, and bDMARDs.[26,28] Furthermore, MTX therapy is associated with a reduction in cardiovascular morbidity and mortality in patients with RA, important given the strong association between RA and cardiovascular disease.[25] Optimization of MTX therapy also involves appropriate dose titration, adequate trial duration, and folate supplementation. Regardless of disease duration, ACR recommends that in the setting of low, moderate, or high disease activity, a trial of MTX as monotherapy may be started initially, with success predicted in 25% to 50% of individuals within 1 year.[28]

In the setting of moderate or high disease activity unresponsive to csDMARD monotherapy, EULAR recommends use of csDMARD combination therapy. csDMARD combination therapy with MTX may also be considered in the setting of moderate or high disease activity with poor prognostic features (i.e., functional limitation, extra-articular disease, positive RF or anti-CCP, and bony erosions). The most common combination is MTX, SSZ, and HCQ, which has been shown to attain treatment goals faster and with less therapy intensification than MTX monotherapy.[73] Culmination of current data suggests that combination csDMARD therapy may be superior to MTX monotherapy, but results remain controversial because of limitations of the studies themselves. Ultimately, MTX as monotherapy or in combination with other csDMARDs are both appropriate as first-line therapy and selection is determined by patient-specific factors.[26] In the setting of MTX contraindication or intolerance, LEF or SSZ, alone or in combination, may be considered as first-line csDMARDs instead. Both agents have demonstrated similar efficacy compared to MTX.[74,75] In addition to combination csDMARD therapy, ACR also considers addition of a bDMARD (either TNF inhibitor or non-TNF bDMARD) as a viable treatment strategy in the setting of csDMARD monotherapy failure in either early (disease duration <6 months) or established (disease duration ≥6 months) RA. The addition of tofacitinib may also be considered for patients with established RA and moderate-to-high disease activity.[28]

If desired response is not achieved with optimized dosing of the first-line treatment approach within the desired time frame, step-up therapy is warranted. If poor prognostic factors are not present, EULAR recommends the patient trial another csDMARD(s) (i.e., LEF, SSZ, and/or MTX as mono- or combination therapy). If prognosis is poor, then addition of a bDMARD to current csDMARD therapy is warranted. Ultimately, for patients on csDMARD therapy who remain unresponsive, bDMARDs should be initiated as add-on therapy to the csDMARD.

For choice of initial bDMARD, EULAR recommends TNF inhibitors, abatacept or tocilizumab, and in certain clinical scenarios, rituximab, as add-on therapy.[26] While TNF inhibitors have a larger evidence base and extended history of use compared to the non-TNF agents, more recent trial data have not triggered safety concerns for the newer agents.[76–79] Rituximab may be considered as a first-line bDMARD in patients having certain contraindications to other bDMARDs such as recent lymphoma, since this agent is not associated with malignancy.[80–82] ACR gives no preference to any bDMARD over another. Anakinra, the IL-1 inhibitor, is not included in either ACR or EULAR recommendations given lack of efficacy when compared to other bDMARDs and its minimal use in clinical practice.[26,28]

Triple csDMARD therapy has been shown to be non-inferior to combination MTX and TNF inhibitor therapy. There is a lack of trial data comparing csDMARDs to other non-TNF bDMARD agents.[82] It is preferred that the bDMARDs be used in combination with either MTX or other csDMARDs rather than as monotherapy.[28] Furthermore, even if clinical response is achieved with combination therapy, the csDMARD(s) should not be discontinued. If a patient truly cannot be treated with csDMARDs, consideration may be given to monotherapy with etanercept, adalimumab, certolizumab pegol, abatacept or tocilizumab.

If a patient has an inadequate response to the initial bDMARD trial, another bDMARD trial is warranted. There is no preferred step-up bDMARD and choice is dependent on patient-specific factors. However, if a TNF inhibitor was initially chosen, or if a patient has failed successive TNF inhibitor trials, changing to a non-TNF bDMARD is recommended. If a non-TNF bDMARD was initially chosen, switching to another non-TNF bDMARD is preferred. Finally, while indicated for individuals with moderate-to-severe RA who have failed MTX therapy, given the lack of clinical experience and safety data compared to bDMARDs, tofacitinib may be considered following multiple bDMARD treatment failures (i.e., at least one TNF inhibitor and two non-TNF bDMARDs).[26,28]

QUANTIFYING RESPONSE TO DRUG THERAPY

RA disease remission is the highest aim of therapy and has become more realistic as medications capable of halting or slowing disease progression are now widely available and commonly used in clinical practice. The ACR and EULAR consider patients with RA in clinical trials to have achieved remission if either of the following occurs: (1) tender joint count, swollen joint count (of 28 joints), C-reactive protein in mg/dL, and patient global assessment scores (scale of 0–10) are all less than 1 or (2) Simplified Disease Activity Index is less than 3.3.37 (Table 44-3). The proportion of patients able to achieve remission with this validated clinical assessment tool is adequate enough to encourage adoption of these criteria in standard practice. If disease remission is unattainable, then minimizing disease activity to provide pain relief, maintain activities of daily living, maximize quality of life, and slow joint damage become primary targets.

Figure 44-6 2015 American College of Rheumatology recommendations for the treatment of established rheumatoid arthritis. (Redrawn from Singh JA et al. 2015 American College of Rheumatology guideline for the treatment of rheumatoid arthritis. Arthritis Rheumatol. 2016;68(1):12.)

Table 44-3

Provisional Criteria for Rheumatoid Arthritis Remission in Clinical Trials from the American College of Rheumatology/European League Against Rheumatism

A patient with rheumatoid arthritis is considered to be "in remission" if either of the following applies:

1. Boolean-based definition
   At any time, patient must satisfy ALL of the following:
   Tender joint count ≤1[a]
   Swollen joint count ≤1[a]
   C-reactive protein ≤1 mg/dL
   Patient global assessment ≤1 (on a 0–10 scale)[b]
2. Index-based definition
   At any time, patient must have a Simplified Disease Activity Index score of ≤3.3[c]

[a] For tender and swollen joint counts, use of a 28-joint count may miss actively involved joints, especially in the feet and ankles, and it is preferable to include feet and ankles also when evaluating remission.

[b] For the assessment of remission, the following format and wording is suggested for the global assessment questions. Format: a horizontal 10-cm visual analog or Likert scale with the best anchor and lowest score on the left side and the worst anchor and highest score on the right side. Wording of question and anchors: For patient global assessment, "Considering all of the ways your arthritis has affected you, how do you feel your arthritis is today?" (anchors: very well–very poor). For physician or assessor global assessment, "What is your assessment of the patient's current disease activity?" (anchors: none–extremely active).

[c] Defined as the simple sum of the tender joint count (using 28 joints), swollen joint count (using 28 joints), patient global assessment (0–10 scale), physician global assessment (0–10 scale), and C-reactive protein level (mg/dL).

Source: Felson DT et al. American College of Rheumatology/European League Against Rheumatism provisional definition of remission in rheumatoid arthritis for clinical trials. Arthritis Rheum Dis. 2011;70:404–413.

In active disease, successful implementation of the treat to target approach requires reevaluation of pharmacologic therapy every 1 to 3 months. Therapy adjustment no later than 3 months into the treatment course is warranted because if there is no improvement by this time then it is unlikely that continuing the same course will achieve satisfactory results. Once treatment targets have been achieved, monitoring may occur less frequently every 6 to 12 months. In patients with good response, glucocorticoids should be the first medications tapered and withdrawn, and if remission is sustained then tapering and discontinuing DMARD therapy (all types) may be considered.[28] This is a conditional ACR recommendation; while the quality of evidence supporting this recommendation is low in terms of the risk of disease exacerbation/recurrence, the long-term risk and cost of continuing therapy that is potentially unnecessary makes this a valid consideration.

Evaluating treatment response using validated clinical assessment tools yield a more accurate assessment of disease activity and improve the likelihood of attaining disease remission through modifications of drug therapy.[87,88] ACR has defined response criteria; however, these are designed for clinical research and may not be practical for clinical practice.[89] Although there is no single tool adopted as the standard of practice in the clinical setting, there are various other validated assessment tools that are advantageous for objectively evaluating disease activity and tracking disease progression (Table 44-4). These tools use various combinations of 28-tender joint count, acute phase reactant measures, pain and function assessments, and patient and physician global assessments of disease activity to determine disease activity. For example, The Clinical Disease Activity Index (CDAI) and the Simplified Disease Activity Index (SDAI) scores are determined through a simple sum of swollen joint count, tender joint count, patient global disease activity, and evaluator global disease activity (both measured by a visual analog scale). However, the SDAI includes CRP in the summation, whereas the CDAI does not.[90] It is important to note that all of these tools have distinctly defined threshold scores corresponding to high disease activity, low-to-moderate disease activity, low disease activity, and remission, although there is little agreement among the tools in terms of classifying a patient's RA activity level. Choice of tool is typically practice-specific.

The scoring tools listed above should be used in conjunction with radiographic evaluation to determine RA course and treatment strategy. Conventional radiography was previously considered the gold standard, but imaging via computed tomography, ultrasound, and magnetic resonance imaging is now available and may offer some benefit in improved resolution compared with standard radiograph technology.[91] Radiographic changes occur in more than half of patients categorized in remission and tracking these can help clinicians objectively evaluate arthritis-related joint damage.[92]

Table 44-4

Tools Used to Measure Disease Activity in Rheumatoid Arthritis

Measurement Tool	Score Range	Thresholds of Disease Activity		
		Low	Moderate	High
Disease Activity Score in 28 joints	0–9.4	≤3.2	>3.2 and ≤5.1	>5.1
Simplified Disease Activity Index	0.1–86.0	≤11	>11 and ≤26	>26
Clinical Disease Activity Index	0–76.0	≤10	>10 and ≤22	>22
Rheumatoid Arthritis Disease Activity Index	0–10	≤2.2	>2.2 and ≤4.9	>4.9
Patient Activity Scale (PAS) or PASII	0–10	≤1.9	>1.9 and ≤5.3	>5.3
Routine Assessment Patient Index Data	0–30	≤6	>6 and ≤12	>12

Tools incorporate multiple variables such as number of swollen joints and tender joints, erythrocyte sedimentation

Tools incorporate multiple variables such as number of swollen joints and tender joints, erythrocyte sedimentation rate, and measures of general health or global disease activity.

Pharmacologic Treatment

NONSTEROIDAL ANTI-INFLAMMATORY DRUG THERAPY

CASE 44-1, QUESTION 4: T.W. will be treated with a DMARD and concurrent NSAID therapy initially to rapidly control inflammation and swelling. What is the role of NSAIDs in the treatment of T.W.'s RA and which is the NSAID of choice?

T.W.'s clinical presentation clearly warrants DMARD therapy (see Case 44-5, Question 4, and Clinical Use of Disease-Modifying Agents section). The purpose of NSAID therapy, which has no disease-modifying activity, is to provide rapid pain relief and reduction of joint inflammation primarily as bridge therapy while awaiting onset of DMARD activity, which could take weeks to months.[39] In general, there is no NSAID of choice for treatment of RA.[13,93] There is no significant difference among the NSAIDs in efficacy, and it is difficult to predict a given patient's response to a particular agent. The selection of an NSAID is based primarily on patient preference, convenience, cost, and safety.[39,40] A 1- to 2-week trial of any NSAID (Table 44-5) at a moderate-to-high dose on a scheduled basis (i.e., not as needed) is the best method of determining anti-inflammatory efficacy. The analgesic and antipyretic effects are relatively prompt in onset.

Although aspirin at high doses is just as effective as other NSAIDs, it is seldom used today because of well-documented gastrointestinal (GI) toxicity and the availability of other safer and more convenient NSAIDs.[39,40,94] Serum salicylate levels correlate well with both efficacy and toxicity.[93] Anti-inflammatory effects of aspirin can be achieved with dosages sufficient to provide serum salicylate concentrations of 15 to 30 mg/dL. Typically, 5 to 7 days of therapy are needed before steady-state serum concentrations of salicylate are attained. A reasonable initial aspirin dose is 45 mg/kg/day divided into 4- or 6-hour intervals; however, the anti-inflammatory dose of aspirin varies widely because of interindividual variations in metabolism. Nonacetylated salicylates are weak inhibitors of COX in vitro and have less GI toxicity than aspirin, but the risks of GI and renal toxicity are similar to nonselective NSAIDs.[40,94]

The nonaspirin NSAIDs have important differentiating properties, and individualizing selection based on these characteristics is warranted in all patients such as T.W.[93] For example, several NSAIDs increase the risk of MI, with diclofenac, meloxicam, and indomethacin showing the highest risk of thrombosis, although celecoxib and ibuprofen at high doses also carry relatively high cardiovascular risk. Naproxen appears to have the best cardiovascular safety profile.[95,96]

Longer-acting NSAIDs such as piroxicam and ketorolac have been associated with a higher frequency of peptic ulcer disease and GI bleeding, and should be avoided. Other NSAIDs, depending on their COX-2 selectivity, have varying GI toxicity profiles with naproxen conferring moderate risk and ibuprofen lower risk.[97,98] The selective COX-2 inhibitor celecoxib, at least with short-term use, is associated with a 20% lower risk of GI bleeding than traditional NSAIDs.[99] Because this agent does not interfere with COX-1—the isozyme responsible for production of the stomach's mucous lining and for reduced acid secretion—in theory COX-2 inhibitors reduce inflammation as effectively as nonselective NSAIDs while reducing the risk of GI toxicity. However, concurrent daily low-dose aspirin use appears to negate any benefit of COX-2 inhibitor therapy on lowering ulcer risk.[100]

Indomethacin penetrates the blood–brain barrier better than any other NSAID, achieving levels in the cerebrospinal fluid of up to 50% of serum levels. As a result, the incidence of central nervous system side effects of indomethacin such as dizziness often precludes the use of optimal anti-inflammatory doses, particularly in the elderly.[101]

A low-cost NSAID (e.g., naproxen and ibuprofen) with a good safety profile is a good choice for T.W. because she is relatively young and does not have any concomitant illnesses. If convenience of administration is a more important consideration, a longer-acting NSAID (e.g., naproxen) would be preferable. If the first agent chosen is ineffective or not well tolerated, other NSAIDs can be tried to identify the optimal one for this patient.

CASE 44-1, QUESTION 5: Naproxen 500 mg twice daily has been prescribed for T.W. If T.W. were to experience dyspepsia during therapy, should she be given antiulcer prophylaxis or a COX-2 selective NSAID at this time? What is the correlation between dyspepsia and gastroduodenal mucosal injury? What instructions regarding NSAID therapy should be provided to T.W., especially with regard to GI problems?

Patients should be informed that NSAID therapy is being prescribed to provide relief of pain and inflammation associated with RA, but that it will not slow or stop the progression of the disease. It should be explained that the latter can only be accomplished by DMARD therapy. Patients should also understand that moderate-to-high daily doses of NSAIDs are required for anti-inflammatory activity, as opposed to analgesic and antipyretic effects which can be achieved with single and low doses.

About 5% to 15% of patients with RA discontinue NSAID therapy because of dyspepsia, and about 1.3% of patients taking NSAIDs for RA experience a serious GI complication. As expected, the rate is somewhat lower for patients using NSAIDs for osteoarthritis (0.7%) because these patients generally use analgesics only on an as-needed basis. Serious NSAID-induced GI complications account for about 103,000 hospitalizations annually in the United States and approximately 16,500 NSAID-related deaths each year.[98,102] Although these figures warrant concern, most patients who experience NSAID-induced dyspepsia suffer only superficial and self-limiting injury. Nevertheless, prevention of NSAID-induced GI bleeding should be an important focus, particularly in high-risk patients.

Patients should be taught to recognize the signs and symptoms of GI bleeding (e.g., nausea, vomiting, anorexia and gastric pain) including melena (described to the patient as "dark, tarry stool") and emesis of coagulated blood (described to the patient as "coughing or vomiting up what seems to be coffee grounds"). It should be emphasized that GI bleeding can occur without gastric pain. The patient should be instructed to contact their health care provider immediately for further instructions if any of these signs or symptoms occurs.

Gastroduodenal mucosal damage induced by NSAIDs primarily results from inhibition of COX-1 in the mucosal lining.[102] This inhibition of COX-1 decreases bicarbonate secretion, mucosal blood flow, formation of protective mucus, proliferation of gastric epithelium, and the ability of the mucosa to resist injury. Topical damage to the GI mucosa can occur from NSAIDs, but direct injury plays a smaller role than COX-1 inhibition. Table 44-6 provides a comparison of COX-1 and COX-2 isoforms.

Table 44-5

Some Nonsteroidal Anti-Inflammatory Drugs

NSAID Generic Name (Brand Name)	Product Availability	Usual Dosing Interval	Maximum Daily Dose (mg)
Salicylates (Acetylated and Nonacetylated)[a]			
Aspirin, enteric-coated[b]	Tablets: 325 mg; 325, 500, 800, 975 mg SR	QID	4,000
Salsalate (Disalcid)[b]	Tablets: 500, 750 mg	BID–TID	4,800
Magnesium choline salicylate (Trilisate)[c]	Tablets: 500, 750, 1,000 mg	Daily–TID	4,800
	Liquid: 500 mg/5 mL		
Propionic Acid Derivatives			
Fenoprofen (Nalfon)[b]	Capsules: 200, 300 mg	TID–QID	3,200
Flurbiprofen (Ansaid)[b]	Tablets: 50, 100 mg	BID–QID	300
Ibuprofen (Motrin)[b]	Tablets: 200, 400, 600, 800 mg	TID–QID	3,200
	Suspension: 100 mg/5 mL		
Naproxen (Naprosyn)[b]	Tablets: 250, 375, 500 mg; 375, 500 mg SR	BID	1,500
	Suspension: 125 mg/5 mL		
Naproxen sodium	Tablets: 275, 550 mg	BID	1,375

(Anaprox)[b]			
Oxaprozin (Daypro)[b]	Tablet or capsule: 600 mg	Daily	1,800
Acetic Acid Derivatives			
Diclofenac (Voltaren XR)[b]	Tablets: 25, 50, 75 mg DR; 100 mg XR	BID–TID	200
Etodolac (Lodine, Lodine XL)[b]	Capsules: 200, 300 mg	BID–TID	1,200
	Tablets: 400, 500 mg; 400, 500, 600 mg XL	XL: Daily	XL: 1,000
Indomethacin (Indocin, Indocin SR)[c]	Suppository: 50 mg	TID	
	Suspension: 25 mg/5 mL	TID–QID	200
	Capsules: 25, 50 mg; 75 mg SR	SR: Daily–BID	SR: 150
Ketorolac (Toradol)[b]	Tablet: 10 mg	QID	40
Nabumetone (Relafen)[b]	Tablet: 500, 750 mg	Daily	2,000
Sulindac (Clinoril)[b]	Tablets: 150, 200 mg	BID	400
Tolmetin (Tolectin)[b]	Tablets: 200, 600 mg		
	Capsules: 400 mg	TID–QID	1,800
Oxicam Derivatives			
Piroxicam (Feldene)[b]	Capsule: 10, 20 mg	Daily	20
Meloxicam (Mobic)[b]	Tablets: 7.5, 15 mg	Daily	15
COX-2 inhibitors			
Celecoxib (Celebrex)	Capsules: 50, 100, 200, 400 mg	BID	400

[a] Highly variable half-life; anti-inflammatory doses associated with salicylate serum concentrations from 15 to 30 mg/dL.

BID, 2 times a day; COX-2, cyclo-oxygenase-2; DR, delayed release; NSAID, nonsteroidal anti-inflammatory drug; QID, 4 times a day; SR, sustained release; TID, 3 times a day; XL/XR, extended release.

Dyspepsia can be managed by ingesting the NSAID with meals or a large glass of water; however, these measures usually are ineffective in preventing GI ulcers. In addition, dyspepsia correlates poorly with endoscopically confirmed mucosal injury.[102–104] Histamine type 2 (H_2) receptor antagonists (e.g., ranitidine, famotidine) significantly reduce dyspepsia among NSAID users; however, NSAID users with RA who take an H_2-receptor antagonist as needed might have a higher risk of developing serious GI complications compared with those who do not take these medications (odds ratio, 2.14; 95% confidence interval, 1.06–4.32).[105] The suppression of dyspepsia symptoms can give a false sense of security to the patient and physician, leading to higher doses of NSAIDs and increased risk of major gastropathy. Also, routine use of H_2-receptor antagonists is associated with tachyphylaxis.[106] Therefore, H_2-receptor antagonists are not recommended for routine use in asymptomatic patients receiving NSAIDs. Proton-pump inhibitors (PPIs; e.g., lansoprazole, omeprazole) relieve dyspepsia better than H_2-receptor antagonists and prevent the development of NSAID-induced gastroduodenal ulcers.[105,107] They are safe and effective for the treatment of NSAID-induced dyspepsia and should be considered if symptoms develop in T.W.

Table 44-6

Comparison of Cyclo-Oxygenase-1 and Cyclo-Oxygenase-2 Isoforms

	COX-1	COX-2
Expression: continuous or induced	Primarily continuous, although some evidence of induction	Primarily induced, but present continuously in several organs
Common organs/tissues	Nearly all organs, including stomach, kidneys, platelets, vasculature	Induced at sites of inflammation and neoplasms
		Continuously active in kidneys, small intestine, pancreas, brain, ovaries, uterus
Primary role	Housekeeping/maintenance	Inflammation, repair, neoplasia
	May be important when induced in response to inflammation	May be important in housekeeping/maintenance of organs that continuously express COX-2

COX, cyclo-oxygenase.
Source: Hawkey CJ. COX-2 inhibitors. Lancet. 1999;353:307.

Effective prevention options for reducing the risk of NSAID-induced ulcers and related complications include a PPI, double the maximal dose of H_2-receptor antagonists, and misoprostol. PPIs are the most efficacious and best tolerated cotherapies with NSAIDs to reduce the risk of peptic ulcers and ulcer complications. Double maximal doses of H_2-receptor antagonists have demonstrated a reduction in NSAID-induced endoscopic peptic ulcers; however, no study has demonstrated that double-dose H_2-receptor antagonists prevent ulcer complications and PPIs remain significantly more effective. Misoprostol, a prostaglandin E_1 analog, is most effective when given at the full dose of 200 mcg 4 times daily; however, intolerable GI upset, particularly diarrhea and abdominal cramping, frequently leads to discontinuation of therapy at this dose. Lower doses are usually prescribed (200 mcg 2 or 3 times daily) with better tolerance but lower efficacy. Sucralfate or antacids are not effective in preventing NSAID-related GI injury.[107]

Routine concomitant antiulcer prophylactic therapy is not warranted for all patients taking NSAIDs; rather the risk for GI ulcer development must be assessed to determine the need for preventive measures. Established risk factors for NSAID-induced GI bleeding include advanced age (>65 years), history of ulcers (a history of complicated ulcers, particularly recent, puts patient at high risk), concurrent use of other ulcer-promoting medications (e.g., corticosteroids, aspirin and anticoagulants), and high-dose NSAID therapy. Patients can be grouped into high, moderate, or low risk of NSAID-induced GI toxicity based on these risk factors. High-risk patients (>2 risk factors) should avoid NSAID therapy or take a COX-2 inhibitor instead along with either a PPI or a misoprostol. Moderate-risk patients (one or two risk factors) should take a PPI or misoprostol with an NSAID; naproxen is the preferred NSAID for high–cardiovascular-risk patients. Low-risk patients (no risk factors) do not need concurrent GI protective therapy and should receive a relatively less GI toxic NSAID at the lowest effective dose.[107] Without risk factors other than NSAID use, T.W. does not need concurrent ulcer prophylaxis or a COX-2 selective NSAID at this time, although a less toxic agent such as naproxen or ibuprofen should be chosen.

Helicobacter pylori infection increases the risk of peptic ulcers in individuals taking NSAIDs.[107] A meta-analysis demonstrated that H. pylori eradication significantly reduced the risk of endoscopic ulcers among patients who had not started NSAID therapy; however, eradication did not lower risk among patients who were already receiving NSAIDs.[108] Therefore, H. pylori testing, and treatment if positive, should be considered for all patients prior to starting chronic NSAID therapy.[107]

Active NSAID-induced gastroduodenal ulcers are best treated by discontinuing the NSAID and initiating a PPI. PPIs are preferred over H_2-receptor antagonists because of greater efficacy, rapid healing rates, and a shorter duration of treatment (4–8 weeks).[109] If discontinuation of the NSAID is not feasible, ulcer healing can still be accomplished with a PPI but requires a longer duration of therapy (8–12 weeks).[109,110] Patients who test positive for H. pylori should undergo H. pylori eradication therapy. Other GI treatments, such as misoprostol and antacids, are ineffective for managing active NSAID-induced ulcers.

CASE 44-2

QUESTION 1: C.S., a patient who was hospitalized for evaluation and treatment of his RA, has a history of aspirin allergy. Are other NSAIDs contraindicated for this patient?

C.S. should be asked to describe his reaction to aspirin to determine whether his symptoms are consistent with a hypersensitivity reaction or with a less serious intolerance issue. Many patients who claim to be allergic to aspirin merely experience GI distress. Aspirin is not contraindicated in these patients and tolerance may be improved if the medication is administered with food or as an enteric-coated preparation.

True aspirin hypersensitivity, especially in association with asthma, is a cause for serious concern because exposure can precipitate an acute, life-threatening, bronchospastic reaction.[111] Between 6% and 15% of asthmatics have a history of aspirin-induced bronchospasm; it occurs more often among women than men and rarely in children. The prevalence of aspirin-induced asthma increases with the presence of nasal polyps. Aspirin-sensitive patients can experience a high degree of cross-reactivity to all nonselective NSAIDs; therefore, these agents should be avoided especially in patients who have a history of aspirin-induced asthma.

On the other hand, COX-2 inhibitors have been used safely in aspirin-sensitive asthmatics.[112–114] In theory, COX-2 inhibitors might be safer because they allow COX-1 to continue producing prostaglandin E_2. Prostaglandin E_2 is an important mediator of multiple physiologic processes, including reduction of leukotriene synthesis, suppression of the release of inflammatory mediators from mast cells, and prevention of aspirin-induced bronchoconstriction.

Aspirin desensitization, which is followed by daily aspirin therapy, is an effective treatment option for most patients with aspirin-induced asthma.[111] Patients who appear to benefit the most include those who rely heavily on systemic corticosteroids or with recurrent nasal polyps.

CASE 44-3

QUESTION 1: A.L., a 53-year-old woman with RA, recalls receiving aspirin long ago, but discontinued it because of “ringing in my ears all the time!” Is this a symptom related to aspirin?

Aspirin-induced tinnitus (i.e., a ringing or high-pitched buzzing sensation in the head) is noticeable to most patients with normal hearing when aspirin serum levels reach 10 to 30 mg/dL; however, in some patients tinnitus might not be encountered until serum levels exceed 25 mg/dL.[93] Serum salicylate concentrations are usually within therapeutic range when tinnitus is apparent. As a result, tinnitus has been used to titrate patients on aspirin to therapeutic doses. It is important to note that patients with preexisting hearing loss might not experience tinnitus despite potentially toxic concentrations.[115]

CASE 44-3, QUESTION 2: A.L. is scheduled to have dental surgery. She states that she is currently taking an aspirin-like product for arthritis pain. Why is it important to know the specific NSAID she is taking?

Aspirin, nonacetylated salicylates, nonaspirin NSAIDs, and COX-2 inhibitors have differing effects on platelet function. Nonaspirin NSAIDs can prolong bleeding times by inhibiting platelet aggregation, but these drugs bind reversibly to COX, resulting in transient platelet inhibition.[93] As a result, if A.L. is taking a nonaspirin NSAID, it should be discontinued approximately 5 half-lives before surgical procedures. For most NSAIDs, the impairment of platelet aggregation is reversed within 2 days after the discontinuation.

Nonacetylated salicylates have minimal effects on COX and platelet function and are of little concern in presurgical patients. Likewise, COX-2 inhibitors are not expected to alter platelet function because COX-2 is not found in platelets.[116]

Aspirin is an irreversible inhibitor of COX and impairs platelet aggregation throughout the life of the platelet. It can prolong bleeding time for several days, which may not normalize until new, unbound platelets are released into circulation. This process may take 3 to 6 days after discontinuation of aspirin; however, this does not always necessitate holding aspirin prior to every procedure. If A.L. is also taking low-dose aspirin chronically, whether or not aspirin may be continued prior to surgery depends on the indication for aspirin and type of surgery. For minor dental procedures, low-dose aspirin can usually be continued.[117,118]

CASE 44-4

QUESTION 1: R.Z. is a 28-year-old woman who is planning a pregnancy and is concerned about the possible effects of NSAIDs on her baby. What are the risks to the fetus with uninterrupted consumption of NSAIDs? What are maternal- and lactation-related effects of these medications?

Although NSAIDs, including aspirin, are not teratogenic, they must be used cautiously in women who are pregnant and who plan to breast-feed infants.[119] Fetal effects of NSAIDs include possible premature ductus arteriosus closure, increased cutaneous and intracranial bleeding, transient renal impairment, and a reduction in urine output. High doses of aspirin (greater than 3 g/day) and NSAIDs can inhibit uterine contractions, resulting in prolonged labor. The use of NSAIDs can also increase peripartum blood loss and anemia. Aspirin and nonaspirin NSAIDs should be used sparingly and at the lowest effective doses during pregnancy and discontinued at least 6 to 8 weeks before delivery to minimize adverse fetal and maternal effects.

Aspirin generally should be avoided for women who plan to nurse their baby because salicylate serum concentrations in breast-fed neonates raise concerns about the potential for metabolic acidosis, bleeding, and Reye syndrome. Nonaspirin NSAIDs are generally compatible with breast-feeding, with the best evidence supporting the use of ibuprofen, indomethacin, and naproxen.[120,121]

CASE 44-5

QUESTION 1: T.Z., a 68-year-old man with heart failure previously managed with furosemide 40 mg/day, digoxin 0.125 mg/day, metoprolol 50 mg twice daily, and lisinopril 40 mg/day, returns for a prescription refill of ibuprofen 600 mg 3 times daily, which he takes for his RA. During the past 2 weeks, he has noted increased leg swelling, a weight gain of several pounds, exacerbated shortness of breath, and easy fatigability. Why might these signs and symptoms be associated with ibuprofen use?

Mild fluid retention occurs in approximately 5% of NSAID users, and NSAID-induced kidney disease occurs in less than 1% of patients.[120,121] NSAID therapy should be avoided, if possible, in patients with preexisting heart failure, kidney disease, or cirrhosis.[122] If a patient with these conditions requires NSAID therapy, or patients are taking angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, serum creatinine should be checked soon after NSAID initiation. Inhibition of COX by NSAIDs within the kidney reduces prostaglandin concentrations and unopposed vasoconstriction. Consequently, urine output declines, serum blood urea nitrogen and serum creatinine levels rise, and fluid is retained. In addition, ibuprofen at higher doses is associated with an increased risk of MI, a concern for T.Z. because of his risk of thrombotic cardiovascular events.[95] The provider of T.Z.'s cardiovascular care should be informed of his symptoms of fluid overload, and an alternative to NSAID therapy should be pursued.

CASE 44-5, QUESTION 2: If NSAID therapy is discontinued, what analgesic or anti-inflammatory alternatives are there for T.Z.? What other renal syndromes are associated with NSAID use?

In several studies, sulindac has been associated with fewer adverse effects on the kidney than other NSAIDs.[123] The reasons for this are unclear, but one explanation is that the active sulfide metabolite undergoes renal metabolism and, therefore, might not achieve tissue concentrations within the kidney sufficient to reduce prostaglandin production.[124] Unfortunately, patients do not seem to benefit from sulindac as much as from other NSAIDs, and the evidence overall supporting the safety of sulindac in renal impairment is weak. COX-2 inhibitors do not appear to offer an advantage for renally impaired patients.[123] Although celecoxib has been associated with a slightly lower risk of death and heart failure exacerbation when compared with traditional NSAIDs, it is not a reasonable initial option for T.Z. because celecoxib is also associated with an increased risk of MI and it may contribute to worsening of heart failure.[125]

NSAIDs should be used at their lowest effective doses for minimal periods for T.Z. High-dose NSAIDs should be avoided owing to increased MI risk. Although acetaminophen is not an anti-inflammatory agent, it can provide analgesic relief. Intra-articular corticosteroid injections can be useful if inflamed joints are limited in number, or a short course of oral corticosteroids can provide rapid control of inflammation while reducing the need

---

for longer courses of anti-inflammatory therapy. If T.Z. is not yet being treated with a DMARD, initiation should be considered immediately because disease-modifying therapy can eventually preclude T.Z.'s need for an NSAID. In the meantime, if an NSAID or short course of systemic corticosteroid is used, close monitoring of renal function and fluid retention status is warranted.

In addition to acute renal failure, NSAIDs can induce various adverse renal effects (e.g., nephrotic syndrome, interstitial nephritis, hyponatremia, abnormalities of water metabolism, and hyperkalemia).[126] The nephrotic syndrome, unlike NSAID-induced acute renal failure, can appear anytime (i.e., from days to years) after initiation of therapy and can resolve as quickly as 1 month, or as long as 1 year, after discontinuation of the NSAID. Hematuria, pyuria, and proteinuria without prior renal disease differentiates nephrotic syndrome from other NSAID-induced renal problems. Histologically, NSAID-induced nephrotic syndrome is characterized by interstitial lymphocytic infiltrates, vacuolar degeneration of proximal and distal tubules, and fusion of epithelial foot processes of glomeruli.

Prostaglandin-mediated inhibition of active chloride transport, regulation of medullary blood flow within the kidney, and antagonism of antidiuretic hormone can be suppressed by NSAIDs. As a result, urine is maximally concentrated, free water clearance is limited, and water retention that is disproportionate to sodium retention can occur. The resulting hyponatremia can be severe and could be potentiated by thiazide diuretics.[126] Local prostaglandin synthesis can also stimulate renin production within the kidney. NSAID therapy can critically attenuate this regulatory mechanism in some situations, resulting in reduced aldosterone-mediated potassium excretion and hyperkalemia.

Although the mechanism is poorly understood, some NSAIDs have been associated with sustained mean arterial pressure increases of 5 to 6 mm Hg,[123,127] presumably the result of COX-2 inhibition and sodium and water retention. Several studies suggest that only patients taking antihypertensive medications experienced NSAID-induced mean arterial pressure elevations, but it is now clear that even normotensive individuals can experience elevations in blood pressure from NSAID use.

CASE 44-5, QUESTION 3: How frequently should T.Z.'s renal and liver function be tested during his NSAID therapy?

Patients at high risk for NSAID-induced renal disease, like T.Z. (see Case 44-5, Questions 1 and 2), should have their serum creatinine levels checked regularly (e.g., weekly) for several weeks after initiation of NSAID therapy because renal insufficiency more commonly occurs early in the course of therapy rather than later.[128] NSAID-induced nephrotic syndrome and allergic interstitial nephritis occur, on average, about 6.6 months and 15 days after NSAID initiation, respectively.[126]

In most cases, liver function testing (LFT) is unnecessary.[128] Although NSAIDs can elevate liver enzymes, severe hepatotoxicity is rare. Abnormal LFTs without clinical symptoms have no impact on patient outcome and have not been associated with severe hepatotoxicity. Patients who seem to be at greatest risk for hepatotoxicity are those with established or suspected intrinsic liver disease and those taking diclofenac. These patients should have LFTs performed no later than 8 weeks after initiation of therapy because liver toxicity manifests early in therapy, if at all.

TRADITIONAL DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

CASE 44-5, QUESTION 4: T.Z. was diagnosed with RA 18 months ago, shortly after symptoms began to manifest. He exhibits no features of a poor prognosis and has low disease activity. Which traditional DMARD (csDMARD) therapies are most appropriate for him?

According to ACR, regardless of disease duration, every RA patient should receive DMARD therapy. Monotherapy with MTX is considered the preferred initial treatment for most RA patients. A high and rapid response rate for all levels of RA severity, relatively low cost and toxicity, and radiographic evidence of slowing joint erosion (which is most rapid during the first several years of active disease) are reasons why MTX is preferred[28] (Fig. 44-6). Other csDMARDs to consider are HCQ, SSZ, and LEF. Although most DMARDs are associated with potentially serious adverse effects, these generally are reversible and seldom lead to serious complications if the patient is monitored appropriately.

In addition, low-dose oral corticosteroids or NSAIDs are often prescribed on an as-needed basis for brief periods of severe disease activity or while awaiting the onset of DMARD action. During periods of disease remission, corticosteroid or NSAID therapy can be discontinued. Safety and efficacy data, which reflect several years of DMARD therapy combined with biologic agents, have been excellent, and the combination is now commonly prescribed for patients who fail MTX monotherapy (see Case 44-7, Questions 9-11).[28] Guidelines for DMARD selection were discussed previously (see Treatment section). Combination DMARD therapy is indicated for more severe or more advanced RA patients (see Case 44-7, Question 8).

Antimalarial Drug Dosing

CASE 44-5, QUESTION 5: Although MTX is considered the initial DMARD of choice for newly diagnosed RA, treatment was initiated with HCQ. What dosages would be appropriate, and when should clinical improvement be expected?

Although the manufacturer's literature recommends an initial HCQ adult dose of 400 to 600 mg/day (310–465 mg of base), dosages for HCQ generally range from 2 to 6.5 mg/kg/day.[28] If the patient responds well, the maintenance dose can be reduced by 50% and the medication continued at a dose of 200 to 400 mg/day (155–310 mg of base). About two-thirds of patients who tolerate HCQ respond favorably. Benefits usually are apparent within 2 to 4 months of therapy, but it can vary between 1 and 6 months. About 37% of patients discontinued HCQ within a year and 54% within 2 years, primarily owing to lack of efficacy.[128]

Risk of Retinopathy

CASE 44-5, QUESTION 6: When being counseled regarding HCQ, T.Z. was told that the drug can cause vision problems. How great is the risk of retinopathy from antimalarials when used for the treatment of RA? What monitoring parameters are appropriate?

HCQ is usually well tolerated. The most serious toxicity, retinal damage and subsequent visual impairment, is rare.[28,128] Risk of retinopathy is increased with high cumulative doses (>800 g), increased age (>60 years), liver disease, and retinal disease. The increased risk of retinopathy in the elderly seems to be related to the increased prevalence of macular disease in this age group. Daily HCQ doses <5 mg/kg for the first 5 years are very rarely associated with increased risk of retinal damage, particularly in patients without renal or hepatic dysfunction. HCQ should not be used for patients with significant renal impairment.

Patients should be instructed to stop therapy immediately and undergo an ophthalmologic evaluation if they are experiencing symptoms of antimalarial-associated retinopathy (e.g., difficulty seeing faces or entire words, glare intolerance, poor night vision, and loss of peripheral vision).[129] The fully developed lesion of antimalarial retinopathy is seen on ophthalmoscopy as a pigmentary disturbance with a characteristic bull's-eye appearance in the macular region. The 4-amino-quinolines bind to melanin, and as a result, concentrate in the uveal tract and retinal pigment epithelium. The retinopathy can be progressive even after discontinuation of the drug.

A baseline eye examination is recommended prior to starting HCQ therapy, then annually after 5 years of treatment.[130] More frequent testing is recommended for patients:

- Taking more than 6.5 mg/kg daily
- Who have received a cumulative dose of >200 mg
- With renal dysfunction
- Who are elderly
- With existing poor visual acuity

Sulfasalazine

CASE 44-5, QUESTION 7: If SSZ were chosen as initial therapy for T.Z., when should therapeutic effects become apparent, and what adverse effects might be anticipated?

The onset of SSZ effect is generally more rapid than that of HCQ, usually providing benefits within 2 to 3 months.[130] Overall, SSZ adverse effects are relatively mild, although SSZ is considered to be slightly more toxic than HCQ. Adverse effects include nausea, abdominal discomfort, heartburn, dizziness, headaches, skin rashes, and, rarely, hematologic effects such as leukopenia (1%–3%) or thrombocytopenia. A complete blood count (CBC) is recommended every 2 to 4 weeks for the first 3 months of therapy, then every 3 months thereafter. Leukopenia, agranulocytosis, or hepatitis are rare, but serious side effects of SSZ usually manifest within the first 2 to 3 months of therapy. To minimize GI-related adverse effects, SSZ is initiated at 500 mg/day or 1 g/day, and the dosage is increased at weekly intervals by 500 mg until 1,000 mg 2 or 3 times daily is reached.

Methotrexate

CASE 44-6

QUESTION 1: S.S., a 41-year-old Asian woman diagnosed with RA, presents with inflammation in both hands (MCP and PIP joints), wrists, elbows, shoulders, knees, hips, ankles, and MTP joints. Objective test results include radiographic evidence of joint erosion in both hands and elbows, positive RF (dilution of 1:1,280), positive anti-CCP at 102 units, and ESR of 78 mm/hour. Her SDAI score is 30. When she initially developed symptoms a year ago, she self-treated with ibuprofen 800 mg 3 times daily; however, pain and inflammation have progressively worsened. ROM testing reveals deficits in wrist flexion and extension (20 degrees bilaterally for both motions; normal, 90 and 70 degrees, respectively), elbow flexion (90 degrees bilaterally with flexion contracture; normal, 160 degrees), shoulder abduction (70 degrees right, 90 degrees left; normal, 180 degrees), and plantar flexion of both ankles (20 degrees bilaterally; normal, 45 degrees). Three firm, pea-sized, nontender moveable subcutaneous nodules are found on both elbows at the ulnar border, two on the right and one on the left. A decision is made to treat S.S. with MTX. Why is MTX a good selection for her?

MTX is recommended as initial DMARD therapy for all patients with RA.[28] S.S. has many indicators of severe disease (e.g., an SDAI score indicating high disease activity [see Table 44-7], multiple joint involvement, extra-articular manifestations [i.e., subcutaneous nodules], radiographic evidence of erosions, elevated ESR, positive anti-CCP, positive RF with a high titer of 1:1,280 [high titers correlate with greater disease severity]). MTX is ideal because it has a rapid onset (usually 1–2 months before a plateau of effectiveness), a high efficacy rate at managing symptoms and slowing disease progression, low toxicity, and a long history of successful use.[28]

Dosing

CASE 44-6, QUESTION 2: How should MTX be dosed and administered to S.S.?

In general, MTX is administered orally at an initial dose of 7.5 mg once a week, usually in a single weekly dose. The dose can also be divided into three equal parts (e.g., starting dose of 2.5 mg every 12 hours for a total of three doses) for patients who are unable to tolerate adverse effects, particularly hepatotoxicity.[40] If S.S.'s RA shows no objective response in 1 to 2 months, the dose is increased to 15 mg/week (or 5 mg every 12 hours for three doses) for at least 12 additional weeks. If no response is seen at this time, then (a) the dose can be increased to the maximum of 25 mg/week, (b) the dose can be administered as a subcutaneous or IM injection to address bioavailability concerns, (c) the same dose can be continued for a longer time, or (d) another DMARD can be added to MTX or MTX can be substituted.[131]

When subcutaneous MTX was compared with oral MTX in a 6-month randomized, controlled trial of 384 MTX-naïve patients with active RA,[132] 78% of patients treated with subcutaneous MTX achieved an ACR-20 response, and only 70% of those treated with oral MTX achieved a similar response. At week 16 of this study, patients treated with oral MTX, who failed to attain an ACR-20 response, were switched to subcutaneous MTX; patients treated with subcutaneous MTX who failed to attain an ACR-20 response were given a larger MTX dose (20 mg) subcutaneously. The patients who were converted from oral dosing to subcutaneous dosing and the patients who were given a larger subcutaneous dose had a 30% and 23% ACR response rate at week 24, respectively. As a result, subcutaneous MTX seems to be more effective than oral MTX and not associated with a higher incidence of adverse effects.

Adverse Effects

CASE 44-6, QUESTION 3: What subjective and objective data should be evaluated for evidence of MTX adverse effects in S.S.?

S.S. should be monitored for nausea and other GI distress, malaise, dizziness, mucositis, and mild alopecia, which are commonly encountered adverse effects associated with low-dose MTX therapy.[128] More serious, but less common, adverse effects include myelosuppression, pneumonitis, and hepatic fibrosis and cirrhosis. A CBC, LFTs, and a serum creatinine concentration should be obtained for her at baseline, monthly for the first 6 months of therapy, and then every 4 to 8 weeks during MTX therapy. Renal dysfunction can result in accumulation of MTX and higher risk of myelosuppression. Interstitial pneumonitis, occurring in <1% of patients, has no known risk factors for development, although it may be more common in patients with a history of lung disease.[130] In addition, interstitial pneumonitis can occur at any time during therapy and at any MTX dosage. A baseline chest radiograph is recommended within the year before MTX initiation. If the patient is found to have preexisting lung disease, MTX treatment should be reconsidered because further pulmonary damage could be devastating to the patient. S.S. also should be monitored carefully for cough, dyspnea on exertion, and shortness of breath at each clinic visit.

MTX-induced liver disease is rare, but increased age, long duration of therapy, obesity, diabetes mellitus, ethanol consumption, and a history of hepatitis B or C increase the risk of hepatotoxicity.[131] MTX should be prescribed with great caution, if at all, in patients with preexisting liver disease. The serum concentrations of liver enzymes commonly are modestly increased

---

after administration for 1 to 2 days. However, MTX should be withheld if liver enzymes increase to 3 times the baseline value or if the liver enzyme serum concentrations remain elevated for sustained periods during therapy. Patients taking MTX should avoid alcohol and be instructed to report symptoms of jaundice or dark urine to their primary care provider. Routine liver biopsies to monitor for MTX-induced hepatotoxicity are unnecessary (see Case 44-6, Question 4).

Liver Biopsy and Methotrexate

CASE 44-6, QUESTION 4: The following laboratory test results were obtained for S.S. before starting MTX:

ALT, 28 IU/L
Aspartate aminotransferase (AST), 30 IU/L
Alkaline phosphatase, 100 IU/L
Albumin, 4.5 g/dL
Total bilirubin, 0.8 mg/dL
Should a baseline liver biopsy be performed before S.S. starts MTX?

Liver biopsy is only recommended at baseline for MTX patients who have a history of heavy alcohol consumption, persistently elevated liver function tests (defined as elevations above the upper limit of normal [ULN] in AST for 5 of 9 tests within a 12-month period [or 6 of 12 if tests are performed every month] or a reduction in serum albumin below normal range), or chronic hepatitis B or C. During therapy, patients with persistently elevated liver functions tests or serum albumin below normal range should have a repeat liver biopsy. Otherwise, routine liver biopsy is unnecessary and not cost-effective.[131] Diligent liver function testing has proven to be highly effective at preventing liver injury.[133] When initiating or escalating methotrexate dosing, ALT with or without AST, creatinine and CBC should be checked every 4 to 6 weeks until stable dosing is achieved, then testing should be repeated every 1 to 3 months thereafter along with screening for adverse effects and hepatotoxicity risk factors at every visit.

Because S.S.'s LFTs are normal and there is not a history of liver disease noted, there is no reason to consider a baseline liver biopsy.

Methotrexate and Folate or Folinic Acid

CASE 44-6, QUESTION 5: When should folate (or folinic acid) be administered to reduce the risk of MTX-related toxicity in S.S.?

Folate supplementation appears to reduce the incidence of several MTX-related adverse effects including GI disturbances, mucositis (mouth or GI ulcerations), and LFT elevations.[133] The current consensus and evidence-based recommendation is >5 mg folic acid daily. Although daily doses of folic acid as low as 1 mg are associated with protection against liver toxicity, GI disturbances are best prevented at doses above 5 mg daily. Although folinic acid has also proven to be effective at lowering GI and hepatotoxicity, doses above 5 mg/week are associated with worsening of arthritis symptoms, consistent with the fact that MTX is a folate antagonist, and folic acid supplementation could adversely impact efficacy.[130,133]

Methotrexate-Related Pulmonary Disorders

CASE 44-6, QUESTION 6: S.S. is treated with MTX 7.5 mg and with folic acid 7 mg orally once a week. Nine weeks later, she returns to the clinic with subjective and objective improvement in morning stiffness, fatigability, and joint tenderness and swelling. However, she has noted increased shortness of breath and dyspnea in the past week. Why might these symptoms be related to MTX?

Pneumonitis, a rare complication of MTX therapy, is characterized by a nonproductive cough, malaise, and fever, progressing to severe dyspnea.[134] Risk factors include older age (over 60 years), previous use of DMARDs, low albumin, and diabetes. Recognition of this unusual reaction is important to ensure that MTX is discontinued before the pneumonitis progresses to respiratory failure. After discontinuation of MTX, pulmonary function improves. Corticosteroids can accelerate improvement in pulmonary symptoms associated with pneumonitis. S.S.'s dyspnea and shortness of breath might be related to MTX. If appropriate tests rule out other causes for her pulmonary complaints, MTX-induced pulmonary toxicity should be considered and MTX treatment discontinued.

Methotrexate Interactions

CASE 44-6, QUESTION 7: What major MTX food and drug interactions need to be discussed with S.S. by her providers?

NSAIDs increase MTX serum concentrations and increase the risk of toxicity.[131] MTX doses should be adjusted cautiously if S.S. is taking NSAIDs concurrently to manage her RA pain. Trimethoprim, frequently used as part of the treatment for urinary tract infections, can increase the risk of MTX-induced bone marrow suppression. The concurrent use of MTX and LEF has been associated with major liver damage, including fatalities; as a result, this combination should be avoided. The inorganic acids in cola drinks appear to delay MTX elimination and can increase risk of toxicity, including renal toxicity; as a result, cola drinks should be avoided with MTX therapy.[135] Because MTX is protein bound and renally excreted, other drugs (e.g., salicylates, probenecid, penicillin, and ciprofloxacin) also might interact with MTX.

Leflunomide: Place in Therapy

CASE 44-7

QUESTION 1: B.W., a 36-year-old woman, has severe, progressive RA and is not responding sufficiently to MTX therapy. Would LEF be a reasonable consideration for her?

LEF, an oral csDMARD, seems to be similar in efficacy to MTX with regard to ACR-20, radiographic response, and work productivity.[28] The onset of benefit (as early as 4 weeks) and the percentage of patients who discontinue LEF therapy because of either lack of efficacy or toxicity are similar for LEF, MTX, and SSZ. The preferred initial csDMARD is MTX because of a long history of safety and efficacy, but LEF is a reasonable consideration as a replacement for MTX-intolerant patients, along with bDMARDs.

Dosing and Monitoring

CASE 44-7, QUESTION 2: How should therapy with LEF be initiated in B.W. and how would you monitor B.W. for adverse effects?

The active metabolite of LEF, A77 1726 or M1, is responsible for virtually all the pharmacologic activity of LEF.[131] The serum half-life of the M1 metabolite is approximately 2 weeks. As a result, LEF should be initiated with a loading dose of 100 mg orally once daily for 3 days to reduce time to steady state, followed by 20 mg once daily. If this dose is not tolerated, the dose should be reduced to 10 mg once daily.

Monitoring for Adverse Effects

Diarrhea (20%–30%), rash (10%), alopecia (10%–17%), and reversible liver enzyme elevations more than 3 times the ULN (2%–4%) are common adverse effects of LEF.[131] Routine laboratory testing includes a baseline ALT followed by monthly ALT testing for several months. When it is evident that ALT results

---

are stable and within normal limits, testing can be performed less often according to the clinician's judgment. Because of the risk of liver toxicity and the need for activation by the liver to the M1 active metabolite, LEF is not recommended in patients with preexisting liver disease, including hepatitis B or C.

Potential hepatotoxicity is the greatest concern with LEF; however, the rate of LEF-induced liver enzyme elevation is not significantly different than MTX. Guidelines for managing potential hepatotoxicity include dosage reduction from 20 to 10 mg/day if ALT increases more than 2 times the ULN.[131] If ALT elevations remain steady between 2 and 3 times the ULN and treatment continuation is desired, a liver biopsy is recommended. If ALT elevations are persistently more than 3 times the ULN despite dosage reduction and cholestyramine administration to enhance elimination (see Case 44-7, Question 3), then the drug should be discontinued and another course of cholestyramine elimination therapy should be given.

Enhancement of Elimination with Cholestyramine

CASE 44-7, QUESTION 3: After 2 months of therapy, B.W. does not respond to LEF and the treatment was discontinued, especially because she is beginning to consider starting a family. What precautions must be taken when discontinuing LEF?

LEF (pregnancy category X) has not been tested in pregnant women, but it greatly increases the risk of fetal death or teratogenicity in animals receiving as little as 1% of human equivalent doses.[131] After discontinuation of therapy, however, up to 2 years may be needed to elapse before plasma M1 metabolite levels of LEF are undetectable. As a result, cholestyramine is recommended for all women who discontinue LEF and who are hoping to become pregnant. After stopping the medication, cholestyramine 8 g 3 times daily is administered for 11 days (which need not be consecutive). Plasma levels of the M1 metabolite are reduced by 40% to 65% in 24 to 48 hours and should become undetectable (<0.02 mg/L) at the end of therapy. B.W.'s blood should be tested at least 14 days apart to verify the absence of the metabolite. If plasma M1 levels remain greater than 0.02 mg/L, more cholestyramine should be administered. Cholestyramine also can be used to enhance elimination of LEF in patients who experience hepatotoxicity or who overdose with this drug. Activated charcoal also can reduce plasma M1 levels by 50% after 48 hours and can be an effective alternative to cholestyramine when LEF overdosages need to be managed.

Hydroxychloroquine and Sulfasalazine

CASE 44-7, QUESTION 4: Would it be reasonable to switch B.W. from MTX to either HCQ or SSZ?

Although both HCQ and SSZ are recommended first-line DMARDs for patients with mild-to-moderate RA, it is more common to add either or both of these to the regimen of patients who are not achieving adequate RA control from MTX.[28] HCQ, usually dosed at 200 to 400 mg daily, is a very well-tolerated DMARD. The greatest adverse effect of concern, retinal damage, is rare and easily prevented with diligent monitoring and dose limitations. SSZ, dosed at 2 to 3 g/day divided into two or three doses, is also well tolerated, although toxicity in general is greater than that with HCQ. GI distress (nausea, anorexia) and rash are common. Although leukopenia, agranulocytosis, and hepatitis are serious side effects, they are rare and, if they do occur, normally manifest in the first 2 to 3 months of therapy. As a result, CBC, LFTs, and renal function testing is recommended more frequently early in the course of therapy. Both HCQ and SSZ appear to be safe in pregnancy.

Although B.W. has failed to respond to MTX and LEF, combinations of csDMARDs and bDMARDs offer greater efficacy with lower toxicity and are therefore preferable.[28]

Traditional Disease-Modifying Antirheumatic Drug Combination Therapy

CASE 44-7, QUESTION 5: Is there evidence to support the early and safe use of DMARDs in combination for B.W.?

Because most RA patients develop joint erosions within the first 2 years of disease, the initiation of disease-modifying agents early in the course of therapy, and using them in combination, has been associated with improved patient outcomes. The rationale for combination therapy is based on the premise that a combination of drugs might improve outcomes because of different pharmacologic mechanisms of action or different sites of actions. A combination of drugs also may allow the use of lower doses of individual drugs, thereby reducing the risk of toxicity while maintaining or possibly increasing efficacy. The early use of combinations of potent disease-modifying agents also can expose the patient to increased risks of drug adverse effects.

Current ACR guidelines support csDMARD combinations as an alternative for patients who fail to reach treatment goals on a single csDMARD but give equal weight to considering other treatment options such as bDMARDs with or without MTX and tofacitinib.[28] Few studies have compared csDMARD combinations with bDMARD therapy. However, one study that randomized patients who failed MTX to receive either MTX + SSZ + HCQ or MTX + infliximab found no difference in clinical measures and serious adverse effects between the two groups after 24 months, although radiographic evidence of disease progression was slightly but not significantly greater in patients receiving MTX + SSZ + HCQ.[136]

In summary, every RA patient, including B.W., should receive csDMARD therapy at or shortly after diagnosis, with MTX monotherapy as preferred initial treatment. Patients who experience loss of efficacy or intolerable adverse effects from MTX can add one or two csDMARDs, or add or substitute a bDMARD or tofacitinib which will be discussed in ensuing sections.

Biologic DMARD Drug Therapy

CASE 44-7, QUESTION 6: After 6 months of treatment with csDMARDs (MTX with LEF, then MTX with HCQ), B.W.'s response is inadequate, her RA remains highly active and she has signs of early joint damage. B.W.'s physician would like to try a TNF-α inhibitor. Is a TNF-α inhibitor an appropriate treatment option for B.W.?

According to the EULAR guidelines, biologic DMARDs should be considered for patients with moderate-to-high disease activity with poor prognostic factors, who do not reach treatment targets with the first csDMARD strategy (MTX alone or in combination with another csDMARD) within 6 months or without poor prognostic factors, who fail a second csDMARD strategy.[28] The ACR guidelines recommend the use of bDMARDs for patients with moderate or high disease activity despite trial with csDMARD monotherapy.[28] There are five TNF-α inhibitors available for the treatment of RA including etanercept, adalimumab, infliximab, certolizumab pegol, and golimumab. Given that B.W. has tried two different csDMARD combinations and continues to have highly active RA with poor prognostic factors, it is time to consider a bDMARD. In fact, patients who fail to respond to csDMARD or bDMARD therapy within 3 months should receive consideration for an alternative treatment. A TNF-α inhibitor, adalimumab, or tocilizumab would all be appropriate choices for a first-line

---

bDMARD according to the EULAR guidelines. However, TNF inhibitors have been available on the market for longer and thus have more robust long-term safety data, which may influence prescribers' confidence in these agents. A TNF-α inhibitor would be an appropriate choice in therapy for B.W. Her MTX therapy should be continued with the selected anti-TNF agent.

CASE 44-7, QUESTION 7: Which TNF-α inhibitor should be started in patient B.W.?

There are five TNF-α inhibitors available for the treatment of RA including etanercept, adalimumab, infliximab, certolizumab pegol, and golimumab. While there are multiple studies describing the efficacy and safety of these agents, there is no consensus on the preferred initial TNF-α inhibitor. The use of each of these medications as well as comparisons between them will be explored here.

TNF-α Inhibitors: Place in Therapy and Dosing

Etanercept (ETA) is the first biologic response modifier to be approved by the FDA for reducing the signs and symptoms of moderate to severe active RA, either alone or in combination with MTX.[44] ETA is a soluble TNF receptor that competitively binds two TNF molecules, rendering both molecules inactive. It is self-administered once weekly by subcutaneous injection at a dose of 50 mg.[44] ETA provides rapid and significant improvement in subjective and objective measures of RA, either alone or in combination with MTX.[43,137] The addition of ETA to MTX therapy has shown greater clinical efficacy when compared with MTX monotherapy.[138] ETA has also been shown to be superior to MTX as monotherapy in the reduction of RA symptoms and disease activity.[139,140] ETA has demonstrated decreased radiographic progression of RA as well as long-term safety and efficacy.[141,142] Etanercept is a reasonable choice for B.W. and should be used in combination with MTX for best results.

Adalimumab (ADA) is a genetically engineered, fully humanized IgG1 monoclonal antibody that has been shown to inhibit the structural damage of RA while reducing clinical signs and symptoms. The recommended dose is 40 mg administered by subcutaneous injection every other week. It is recommended to give ADA in combination with MTX.[45] Patients who cannot or choose not to take MTX may benefit from weekly dosing.[45] When ADA 40 mg every other week was added to the treatment regimen of RA patients receiving stable MTX doses, significantly more ADA-treated patients (67%) achieved an ACR-20 response than those receiving only MTX (14.5%, $p < 0.001$) after 24 weeks.[143] Combination therapy with ADA and MTX was shown to be superior to either MTX or ADA monotherapy for RA symptoms and disease progression.[144] In radiographic data reflecting 1 or 2 years of treatment, ADA has been shown to slow the progression of joint damage. Data also support the long-term efficacy and safety of ADA for more than 8 years.[145] ADA would also be an appropriate choice for B.W. and would require less frequent injections than ETA.

Infliximab (IFX) is a chimeric (mouse–human) IgG antibody directed against TNF. Specifically, IFX is approved in combination with MTX for the treatment of moderate to severe active RA. The recommended dose is 3 mg/kg via intravenous infusion at weeks 0, 2, and 6, then every 8 weeks thereafter. Some patients may benefit from an increase in dose up to 10 mg/kg or a decrease in treatment interval to as often as every 4 weeks.[46] IFX should be given with MTX therapy to prevent the formation of antibodies to infliximab. In a randomized, double-blind, multicenter, placebo-controlled trial of active RA patients who failed to respond adequately to at least 12.5 mg/week of MTX, IFX 3 or 10 mg/kg or placebo was administered every 4 or 8 weeks along with MTX therapy. The signs and symptoms of RA were improved in the IFX groups versus MTX alone. This study was unblinded after 1 year because of radiographic evidence of disease modification in patients receiving IFX. Analysis of radiographic results after 2 years demonstrated that IFX significantly protected against joint erosion.[146] IFX would also be an appropriate bDMARD for B.W., particularly if she prefers less frequent intravenous infusions to self-administration of subcutaneous injections. Patient preferences are an important factor to consider when choosing between the anti-TNF agents.

Certolizumab pegol (CZP) consists of a Fab attached to a 40-kDa PEG moiety. The attachment to the PEG moiety increases the half-life of CZP to approximately 2 weeks, which allows dosing every 2 to 4 weeks.[147] The recommended dosing regimen is 400 mg initially and at weeks 2 and 4 followed by 200 mg every other week or 400 mg every 4 weeks by subcutaneous injection.[47] CZP's unique structure lacks an Fc region, so it may not induce complement- or antibody-dependent cell-mediated cytotoxicity, which has been observed in vitro with adalimumab, etanercept, and infliximab.[148] The efficacy of CZP has been demonstrated in patients with moderate to severe active RA in combination with MTX and as monotherapy.[149–151] In a randomized, double-blind, placebo-controlled study in 619 patients with active RA, significantly more patients met ACR response rates with CZP plus MTX than patients treated with placebo plus MTX ($p < 0.001$).[150] Physical function, as evidenced by the mean change in the HAQ disability index (DI) score, DAS28 remission, and radiographic progression of RA were all improved in the CZP plus MTX group.[150] CZP has shown sustained efficacy and safety over 5 years in patients with active RA.[152] Patient B.W. would also be a candidate for CZP. As with ETA and ADA, CZP is self-administered by subcutaneous injection.

Golimumab (GLM) is a human IgG1 monoclonal antibody specific for human TNF-α. It was created using genetically engineered mice immunized with human TNF. GLM binds to both the soluble and the transmembrane bioactive forms of human TNF. This binding prevents the binding of TNF-α to its receptors, thus inhibiting the biologic activity of TNF-α.[49] GLM shares common characteristics with both adalimumab and infliximab. Similar to adalimumab, GLM is a fully humanized bivalent immunoglobulin monoclonal antibody.[153] GLM is made up of light and heavy chains, which are identical to infliximab, but whereas infliximab is derived from both mice and humans, GLM is completely humanized. GLM is approved for the treatment of moderate-to-severe active RA in combination with MTX.[49] It can be administered by subcutaneous injection or intravenous infusion. The subcutaneous injection is a 50 mg injection dosed every 4 weeks.[49] The dose of the intravenous infusion is 2 mg/kg over 30 minutes as weeks 0 and 4, then every 8 weeks thereafter.[154] Clinical trials have demonstrated GLM efficacy in patients with no previous MTX use and in patients with an inadequate response to MTX or a TNF-α inhibitor.[155–157] A randomized, placebo-controlled trial conducted in 444 patients examined the efficacy of GLM in patients with active RA despite concomitant MTX use.[158] Significantly, more patients in the combined GLM plus MTX group achieved an ACR-20 response compared with the MTX plus placebo group (55.6% vs. 33.1%, respectively, $p < 0.001$), and these results were sustained at 52 weeks.[158] In another study assessing the long-term safety and efficacy of GLM in RA patients who discontinued previous TNF-α inhibitors, GLM treatment resulted in sustained efficacy and safety through 5 years.[158] Given this information, GLM would also be an appropriate treatment option for B.W., and she would have the option of choosing between intravenous or subcutaneous dosing.

There are currently no definitive guidelines recommending one TNF-α inhibitor over another. Direct head-to-head comparisons between the anti-TNF agents are lacking; therefore, prescribers must depend on surveillance data, systematic reviews, and meta-analyses to make clinical decisions regarding comparative efficacy and safety.

Table 44-7

Biologic Disease-Modifying Antirheumatic Drug Dosing Information

Generic (Brand)	Mechanism of Action	Dosage Range	Administration Schedule	Routes of Administration	Can Be Self-Administered?
Infliximab (Remicade)	TNF-α inhibitor	3 mg/kg[a]	Weeks 0, 2, and 6 and then every 8 weeks	IV	No
Etanercept (Enbrel)	TNF-α inhibitor	50 mg	Weekly	SC	Yes
Adalimumab (Humira)	TNF-α inhibitor	40 mg	Every 14 days	SC	Yes
Certolizumab pegol (Cimzia)	TNF-α inhibitor	Initial: 400 mg SC on weeks 0, 2, 4 Subsequent: 200 mg every 2 weeks or 400 mg	Weeks 0, 2, and 4, then every 2 or 4 weeks	SC	Yes

		every 4 weeks			
Golimumab (Simponi)	TNF-α inhibitor	50 mg	Every 4 weeks	SC	Yes
Golimumab (Simponi Aria)	TNF-α inhibitor	2 mg/kg infusion over 30 minutes	Weeks 0 and 4, then every 8 weeks	IV	No
Abatacept (Orencia)	Costimulation modulator, T cell activation inhibitor	Weight based: <60 kg = 500 mg 60–100 kg = 750 mg >100 kg = 1,000 mg	Weeks 0, 2, and 4 and then every 4 weeks	IV	No
		Or			
		125 mg	Once weekly (may be initiated with or without IV loading dose)	SC	Yes
Rituximab (Rituxan)	CD20+ B-cell inhibitor	1,000 mg IV infusion: Initial: 50 mg/hour, may increase every 30 minutes to a maximum rate of 400 mg/hour Subsequent: 100 mg/hour, may increase every 30 minutes to maximum rate of 400 mg/hour[b]	Repeat in 14 days, then discontinue	IV	No
Tocilizumab (Actemra)	IL-6 inhibitor	Initial: 4 mg/kg every 4 weeks Subsequent: Titrate to 8 mg/kg based on clinical response Max: 800 mg/dose (8 mg/kg)	Every 4 weeks	IV	No
		Or			
		Weight based SC dosing: <100 kg= 162 mg every other week, followed by an increase to every week based on clinic response ≥100 kg = 162 mg every week		SC	Yes

Anakinra (Kineret)	IL-1 inhibitor	100 mg	Once daily	SC	Yes

[a] For incomplete response, may increase dose to 10 mg/kg or decrease dosing interval to every 4 weeks.

[b] Premedicate with corticosteroid, acetaminophen, and an antihistamine before each dose.

IL, interleukin; IV, intravenous; SC, subcutaneous; TNF, tumor necrosis factor.

In a mixed treatment comparison of the anti-TNF agents, all of the agents demonstrated significant improvement in clinical response across all outcome measures. However, etanercept and certolizumab demonstrated improved outcomes compared to infliximab, adalimumab, and golimumab. All anti-TNF agents were found to be superior to infliximab.[160] Evidence from national registries have also provided insight into the differences among TNF-α inhibitors in clinical practice. Patients in the Czech National Registry had higher survival rates when treated with adalimumab and etanercept compared to infliximab.[161] Data from the Danish and Swedish national registries have shown the drug continuation rates were significantly higher with etanercept and adalimumab than with infliximab.[145,162,163] In a meta-analysis of Cochrane reviews of six biologics for RA (abatacept, adalimumab, anakinra, etanercept, infliximab, and rituximab), it was found that etanercept was associated with lower rates of withdrawal because of adverse events than either adalimumab or infliximab, and the survival rates with adalimumab and etanercept were better than with infliximab.[164] Given this data, etanercept would be an appropriate choice for B.W. as initial therapy with a bDMARD. Systematic reviews seem to demonstrate that etanercept is well-tolerated in comparison to other bDMARDs and has been associated with superior efficacy. Given no other patient specific factors to guide therapy toward another agent, etanercept would be an appropriate option. (Dosing information for the TNF-α inhibitors can be found in Table 44-7.)

CASE 44-7, QUESTION 8: What side effects will need to be monitored when starting B.W. on etanercept?

TNF-α Inhibitors: Side Effects and Monitoring

The greatest concern with etanercept therapy is the risk of immunosuppression and subsequent serious infections, including sepsis. TNF-α is a key mediator of inflammation and plays a major role in immune system regulation. Post-marketing reports of infections, such as TB, mycobacterial infections, and fungal infections, further reinforce the strong recommendation against the initiation of etanercept therapy in patients with sepsis or any chronic or localized active infection.[44] Mycobacterium tuberculosis skin testing and a baseline chest radiograph should be undertaken before initiation of anti-TNF therapy. Therapy should be postponed for patients identified as having latent TB until appropriate antituberculosis therapy has been completed.[28] Clinicians also must be cautious when prescribing etanercept (or any bDMARD) to patients with a history of recurring infection or with underlying illnesses that predispose them to infection (i.e., diabetes). B.W. should receive a TB skin test, undergo a chest radiograph, and be warned of the potential adverse effects of etanercept, particularly the risk of immunosuppression and subsequent infection. Any sign of infection must be reported immediately to her health care provider.

TNF-α has been implicated in the pathophysiology of heart failure, and increased serum levels of TNF-α seem to be associated with worsening heart failure.[165] Proposed mechanisms contributing to the onset or worsening of heart failure include accelerated left ventricular remodeling, negative inotropic effects, and increased apoptosis of myocytes and endothelial cells. However, despite the association between TNF-α and worsening of heart failure, clinical trials with anti-TNF therapy (which have included etanercept and infliximab) have not reduced mortality and heart failure–related hospitalizations. Furthermore, some trials have shown increased cardiovascular risk.[165] As a result, anti-TNF therapy is not recommended for RA patients with moderate-to-severe (New York Heart Association [NYHA] class III and IV) heart failure. Anti-TNF therapy can be used with caution in patients with mild (NYHA class I and II) heart failure, but patients should be closely monitored for cardiac decompensation.[26,28]

Included in the labeling for all anti-TNF bDMARDs is a warning for increased risk of lymphoma. An increased incidence of lymphoma has been observed among patients with RA receiving any of the available anti-TNF agents; however, causation has not been established because both RA and MTX are associated with an increased rate of lymphoma. In an observational study assessing the risk of lymphoma in patients treated with csDMARDs compared to patients treated with anti-TNF agents, there was no evidence of an increased risk in the anti-TNF cohort.[166] A meta-analysis of patients receiving anti-TNF agents suggested a possible increase in incidence of lymphoma; however, given the low incidence of lymphoma overall, this failed to reach statistical significance.[167] Additionally, the FDA has issued a warning following reports of hepatosplenic T-cell lymphoma, a rare cancer of the white blood cells, in patients being treated with TNF blockers, AZA, or mercaptopurine.[168] The majority of these cases were found in adolescents and young adults with Crohn’s disease or ulcerative colitis. Incidence was also more common in patients on a combination of immunosuppressive agents. Although it is difficult to measure the added risk associated with anti-TNF agents, caution and monitoring is advised.[168] Other adverse effects, in order of decreasing frequency, include headache, rhinitis, dizziness, pharyngitis, cough, asthenia, abdominal pain, and rash.

CASE 44-8

QUESTION 1: S.K., a 71-year-old woman, was diagnosed with RA approximately 15 years ago. Her initial drug therapy included MTX, followed by the addition of SSZ and HCQ, which seemed to keep her RA in near-remission for 5 years. She then began etanercept along with MTX (without SSZ and HCQ) with good results until 1 year ago. In response to declining disease control, infliximab was substituted for etanercept with excellent results. Then last month, she experienced a flare in RA activity. At that time, her CRP was 5.1 mg/dL, ESR was 90 mm/hour, and anti-CCP was positive at 112 units. She also experienced morning stiffness lasting several hours and multiple joints with swelling (n = 26) and tenderness (n = 38). Of note, S.K. has a history of treated skin melanoma 2 years ago. What are the reasonable treatment options for S.K. at this stage of her disease?

Clinical studies have consistently demonstrated that bDMARDs improve the signs and symptoms of RA as well as slow the progression of structural damage. TNF-α inhibitors have long been considered first-line bDMARDs given the availability of long-term data and clinical experience compared to the non-TNF bDMARDs. However, ongoing registry and trial data suggests that the safety profiles of the non-TNF bDMARDs, abatacept, rituximab, and tocilizumab, are consistent with clinical trial results.[26] Some trials have shown superiority of some of these agents over TNF-α inhibitors. TNF-α inhibitors also fail to produce an ACR-20 response in approximately 30% of patients, which is known as primary failure. Even more patients experience acquired resistance to treatment, known as secondary failure, which is defined as a loss of response with time and is illustrated by S.K.[169] Many patients who lose responsiveness to an initial trial of anti-TNF therapy can be successfully treated with an alternative anti-TNF agent.[170] However, studies have also shown that response rates with sequential anti-TNF therapy may be lower and the reasons for initial anti-TNF failure (inefficacy or adverse effects) may be recurrent.[170,171] Therefore, it is important to consider alternative options for the treatment of patients like S.K. with anti-TNF treatment failure.[170,171]

Abatacept (inhibitor of T-cell activation), rituximab (selective depletor of CD20+ B cells), and tocilizumab (anti-IL-6 receptor antibody) have demonstrated excellent efficacy in patients with inadequate response to csDMARDs (e.g., MTX) as well as to anti-TNF therapy.[26,28] Owing to their differing mechanisms of action, each of these agents possesses unique qualities with regard to efficacy and safety. (Detailed dosing information for the bDMARDs can be found in Table 44-7.)

Abatacept

Abatacept (ABT) is a selective costimulation inhibitor of T-cell activation indicated for the treatment of moderate to severe active RA.[52] ABT may be prescribed as monotherapy or in combination with csDMARDs. It can be administered intravenously or subcutaneously. ABT intravenous dosing is based on body weight (500 mg for patients <60 kg, 750 mg for patients 60–100 kg, and 1,000 mg for patients >100 kg) and should be infused over 30 minutes at weeks 2 and 4 after the first dose, then every 4 weeks thereafter.[52] The dose for the subcutaneous injection is 125 mg weekly. The efficacy and safety profiles have been shown to be comparable between the two preparations.[172]

Abatacept has demonstrated efficacy in patients with an inadequate response to MTX as well as in patients with an inadequate response or adverse reactions to TNF-α inhibitors.[52] In a study comparing ABT plus MTX to placebo plus MTX, significantly more patients in the ABT plus MTX group attained ACR-20 response when compared with the ABT plus placebo group (73.1% vs. 39.7%, respectively, $p < 0.001$) and had significant slowing of structural damage progression compared to the patients treated with placebo at 12-month follow-up.[53] ABT efficacy was maintained in the 5-year open-label extension of this trial. Structural damage progression was reduced by 50% in the second year relative to the first year, with approximately half of the patients who completed all 5 years of ABT treatment exhibiting no structural damage progression.[173] Efficacy and safety data from 7 years of ABT therapy indicate that ABT maintains sustained improvements in disease activity and ACR-70 scores during this period, with no change in safety profile.[174] ABT has also demonstrated efficacy in patients with an inadequate response to one or more TNF-α inhibitors, such as S.K.[175,176]

Finally, ABT has also been compared head-to-head with the TNF-α inhibitor adalimumab. In a 2-year study in RA patients with an inadequate response to MTX, ABT and ADA were found to be similar in both efficacy and safety. Overall, patients experienced similar improvement in clinical markers of disease control and progression. While rates of adverse events in both groups were similar, there were more discontinuations because of adverse events in the ADA group (9.5%) compared to the ABT group (3.8%) (95% CI −9.5 to −1.9).[177]

The side effects of greatest concern with ABT include infections such as pneumonia, cellulitis, urinary tract infection, bronchitis, diverticulitis, and acute pyelonephritis. Infections are significantly more common when ABT is combined with anti-TNF therapy; thus, this combination is not recommended.[52] A few case reports of malignancy have been associated with ABT, and patients with chronic obstructive pulmonary disease are noted to suffer from more respiratory-related and nonrespiratory-related adverse effects than patients with chronic obstructive pulmonary disease treated with placebo.[52]

Rituximab

Rituximab (RXB) is a chimeric monoclonal antibody that binds to the antigen CD20 on B cells. It is approved in combination with MTX for the treatment of moderate to severe active RA in patients who have had an inadequate response to one or more TNF antagonist medications.[54] However, according to the EULAR guidelines, rituximab may be considered as a first-line bDMARD in patients with contraindications to other bDMARDs, such as recent history of lymphoma, latent TB with contraindications to chemoprophylaxis, living in a TB-endemic areas or a previous history of demyelinating disease.[26] RXB, provided in 100- and 500-mg single-use vials at a concentration of 10 mg/mL, is administered as two 1,000-mg IV infusions separated by 2 weeks.[54] RXB must be diluted to a final concentration of 1 to 4 mg/mL with either 0.9% sodium chloride or 5% dextrose in water. To reduce the incidence and severity of infusion-related adverse effects, premedication with IV methylprednisolone 100 mg, or its equivalent, 30 minutes before each infusion is strongly recommended; other premedications (e.g., acetaminophen and antihistamine) may also be beneficial. Antihypertensive medications should be discontinued 12 hours before RXB administration to avoid transient hypotension, which has been reported during RXB infusions. RXB must be given with MTX for maximal efficacy based on clinical trials and to help reduce the risk of developing HACA, which occurs in approximately 9% of patients receiving RXB. It is recommended that subsequent courses of RXB be given every 24 weeks. The dosing interval may be decreased on the basis of clinical evaluation, but must be no less than every 16 weeks.[54]

Rituximab has been shown to be effective in patients who have responded inadequately to MTX therapy as well as in patients who have responded inadequately to anti-TNF medications.[178] The REFLEX (Randomized Evaluation of Long-Term Efficacy of Rituximab in RA) trial evaluated the use of RXB plus MTX versus placebo plus MTX in 499 patients with active, long-standing RA who responded inadequately to one or more anti-TNF medications, such as S.K.[179] At 24-week follow-up, significantly more patients in the RXB group demonstrated an ACR-20 response than those in the placebo group (51% vs. 18%, respectively). And in a 56-week follow-up report of the REFLEX trial, RXB significantly inhibited radiographic progression of joint damage.[180] In the 2-year extension of this trial, RXB showed significant and sustained inhibition of joint damage. These findings support the efficacy and appropriateness of RXB for RA patients, such as S.K., who are refractory to anti-TNF therapy.

In the case of failure with one TNF-α inhibitor, patients may be switched to another anti-TNF agent or to a non-TNF agent. While there are no randomized controlled trials providing head-to-head comparisons between switching to rituximab versus a second anti-TNF agent, there are some observational studies to guide therapy. In the SWITCH-RA trial, a global, observational, comparative effectiveness study, rituximab was compared to an alternative TNF inhibitor in patients with RA with a previous inadequate response to one TNF inhibitor. It was found that the change in DAS28-3-ESR at 6 months was significantly greater in the rituximab patients versus the second TNF inhibitor patients (−1.5 vs. −1.1; $p = 0.007$). However, this difference only remained significant for the patients who discontinued the initial TNF inhibitor because of inefficacy, but not in those who discontinued because of intolerance.[181] Similar results have been found in other observational studies of initial TNF nonresponders.[182] Clinicians should consider reasons for treatment failure, potential side effects, route of administration, ease of use, cost and patient specific factors when choosing an appropriate therapeutic regimen. There is currently no definitive investigation or recommendation for sequencing of bDMARDs. There is a randomized controlled trial underway comparing ABT, RXB, and other anti-TNF therapy following anti-TNF failure, which is expected to provide further insight upon completion.[183]

Infusion reactions, including severe reactions, can be caused by RXB. Severe reactions typically occur with the first infusion; thus, careful monitoring is warranted and premedication with methylprednisolone 100 mg or its equivalent is recommended 30 minutes prior to each infusion. RXB should be discontinued if a serious reaction occurs. Severe mucocutaneous reactions may also occur in patients receiving RXB. Finally, hepatitis B (HBV) reactivation may occur in patients receiving RXB. Therefore, all patients should be screened for HBV infection prior to initiation. The most common adverse reactions in RA patients receiving RXB include upper respiratory tract infections, nasopharyngitis, urinary tract infections, and bronchitis.[54] RXB has not been associated with any increase in malignancy; therefore, it is preferred over anti-TNF agents in patients with a recent history of cancer.[26]

Since S.K. failed two TNF- inhibitors because of inefficacy, either ABT or RXB would be an appropriate choice. Given S.K.'s history of skin melanoma 2 years ago, RXB would be the preferred agent over ABT in this patient.

CASE 44-9

QUESTION 1: Q.O. is a 55-year-old woman with highly active RA for the past year who cannot tolerate MTX therapy. Her doctor would like to start a bDMARD as monotherapy and would like to know which medication would be best?

Tocilizumab

Tocilizumab is a humanized anti-IL-6 receptor antibody indicated for the treatment of adult patients with moderate to severe active RA, who have had an inadequate response to one or more csDMARDs.[57] TCZ may be administered intravenously or subcutaneously. For the intravenous infusion, the recommended dosage is 4 mg/kg, infused IV every 4 weeks with an increase to 8 mg/kg as needed based on clinical response. The dosing for the subcutaneous formulation is 162 mg per injection either weekly or every other week depending on patient weight and response.[57] The safety and efficacy of the intravenous and subcutaneous formulations have been studied and appear to be comparable. However, an increase in injection site reactions in the subcutaneous TCZ group has been seen.[184] TCZ should not be initiated in patients with an absolute neutrophil count less than 2,000 cells/μL, platelet count less than

100,000 platelets/μL, or in patients who have an ALT or AST value greater than 1.5 times the ULN.[57] TCZ treatment should be interrupted if a patient experiences a serious infection; therapy may be resumed once the infection is controlled.[57]

TCZ has demonstrated efficacy in the treatment of RA as monotherapy, in combination with csDMARDs, and in patients who are refractory to anti-TNF medications.[185,186] In a systematic review of eight RCTS, TCZ at a dose of 8 mg/kg in combination with MTX was shown to statistically significantly decrease disease activity and improve physical function when compared to MTX plus placebo.[187] TCZ has also shown decreased radiographic progression of RA compared to csDMARDs.[185,188] In the RADIATE trial, patients with an inadequate response to one or more TNF-α inhibitors were randomly assigned to receive 8 or 4 mg/kg of TCZ or placebo every 4 weeks for 24 weeks.[186] An ACR-20 response was achieved at 24 weeks by 50.0%, 30.4%, and 10.1% of patients in the TCZ 8 mg/kg, 4 mg/kg, and placebo arms, respectively ($p < 0.001$).[186] Given this information, TCZ would also be a reasonable option for patients who have failed one or more TNF inhibitors, like S.K. from Case 44-8.

Tocilizumab is also approved as monotherapy for RA. In the AMBITION trial, TCZ monotherapy compared to MTX monotherapy and TCZ therapy was found to have a superior ACR 20 response (69.9% vs. 52.5%; $p < 0.001$) and DAS28 <2.6 rate (33.6 vs. 12.1%) at week 24.84. In a study comparing TCZ 8 mg/kg plus MTX, TCZ 4 mg/kg plus MTX, TCZ 8 mg/kg monotherapy, and MTX monotherapy, all groups containing TCZ showed superior DAS28 remission compared to MTX alone. However, only the TCZ 8 mg/kg plus MTX group had consistent superiority in clinical, functional, and radiographic outcomes.[85]

According to the ACR and EULAR treatment guidelines, the standard of care indicates that patients should maintain MTX or csDMARD therapy when a bDMARD is added.[26,28] However, for up to 40% of patients, MTX therapy is discontinued because of intolerance or patient preference and as many as one-third of patients may be taking bDMARDs as monotherapy.[86] Three of the TNF inhibitors (etanercept, adalimumab, and certolizumab pegol) and two of the non-TNF bDMARDs (abatacept and tocilizumab) are approved as monotherapy. In a study comparing ADA and TCZ monotherapy in patients who were either intolerant to MTX or MTX was not an appropriate treatment option, patients in the TCZ group were found to have significantly greater improvement in DAS28 as well as most clinical endpoints when compared to the ADA group.[86] Therefore, TCZ is a reasonable therapeutic option for Q.O. as monotherapy for RA and has demonstrated superiority over at least one anti-TNF agent.[186,188]

When starting TCZ, Q.O. should be monitored for potential side effects. The most serious side effects associated with TCZ therapy include severe infections, GI perforation, and laboratory abnormalities. As with the TNF-α inhibitors, TCZ has a boxed warning for increased risk of developing serious infections, especially those caused by opportunistic pathogens. The risk for infection is increased when TCZ is taken in combination with other immunosuppressant agents (e.g., MTX and corticosteroids). As with the anti-TNF agents, a TB skin test result and chest radiograph must be obtained before initiating treatment. In clinical studies the overall rate of fatal serious infections was low at 0.13/100 patient-years.[57]

TCZ has also been associated with a number of blood chemistry changes including neutropenia, thrombocytopenia, elevated LFTs, and lipid changes. Increases in lipids (total cholesterol, low-density lipoprotein, high-density lipoprotein, and triglycerides) have been shown in clinical trials. Increase in lipids may be caused in part by the decrease in inflammatory activity with TCZ use. Lipid elevations respond to lipid-lowering agents. While clinical trials do not indicate an increase in cardiovascular risk, further studies are necessary to assess the effects of TCZ on cardiovascular risk factors.[189,190]

CORTICOSTEROIDS

CASE 44-10

QUESTION 1: W.M., a 57-year-old man, has progressive RA that has not been responsive to SSZ. He is having difficulty working a full day and is seeking an alternative medication. After a discussion of therapeutic options, W.M. declines MTX therapy and asks to start HCQ. Would it be appropriate to initiate corticosteroids concurrently? And if so, at what dose?

Despite the potential for serious adverse effects with long-term therapy, the judicious use of low-dose corticosteroids represents an important component of treatment during the course of unremitting disease. In addition, low-dose corticosteroids may offer some disease-modifying properties, although this is controversial because of the long-term negative effects of corticosteroid use.[65] The benefit of low-dose glucocorticoid therapy is favorable as long as the course of therapy is short.[28] Considering that W.M.'s RA is sufficiently active to compromise his ability to earn an income, MTX is a much better DMARD selection. Regardless, concurrent initiation of a DMARD and an intermediate-acting corticosteroid (e.g., prednisone in a daily or divided dose of 5–10 mg) is justified.[191] A Cochrane review showed that corticosteroid doses equivalent to ≤15 mg of prednisolone were superior to placebo and NSAIDS for joint tenderness and pain in RA.[192] In large cohort studies, prednisone doses greater than 7.5 mg/day

---

have been associated with a greater than twofold increased risk of cardiovascular events (MI, stroke, and heart failure), as well as the risk of developing hypertension with long-term use (at least 6–12 months).[193,194] Therefore, the lowest effective corticosteroid dose is preferred for the shortest duration of time possible.[28] The onset of action of corticosteroids is relatively rapid, and their immediate benefits will allow W.M. to maintain his current employment and continue taking care of responsibilities at home. The corticosteroid dose can be decreased gradually and eventually discontinued as W.M. begins to respond to HCQ therapy. An important goal of low-dose corticosteroid treatment is to provide bridge therapy until the DMARD therapy becomes effective, in hopes of then being able to taper and discontinue the corticosteroid.

CASE 44-10, QUESTION 2: Would intra-articular corticosteroid injections be a safe and effective treatment option for W.M.?

Intra-Articular Corticosteroids

Intra-articular corticosteroid injections are safe and effective for pain relief in patients with RA. This strategy is most sensible when flaring occurs in one or a few joints.[195] Systemic side effects are minimal when compared with oral corticosteroid therapy. Although onset of action is virtually immediate, effects are often short-lived. W.M. could benefit from the use of intermittent intra-articular corticosteroid injections for the treatment of RA flares.

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis is a heterogenous group of chronic arthritic conditions of unknown etiology, occurring before 16 years of age. It is the most common chronic rheumatic disorder in childhood, afflicting approximately 300,000 children in the United States, affecting all races equally with peak age of onset between two and four. However, new cases are seen throughout childhood and often continue into adulthood, causing significant morbidity and physical disability.[196–198]

Clinical Presentation and Classification

By definition, symptoms of JIA (joint inflammation involving swelling, pain, limited ROM, warmth, and erythema) present before the age of 16 and must last for at least 6 weeks in at least one joint.[199] Similar to other rheumatologic disease classifications, the diagnosis of JIA is a diagnosis of exclusion; infectious, traumatic, and other etiologies must be ruled out first.[200]

As with adult RA, JIA begins with synovial inflammation. Because children often cannot articulate complaints, morning stiffness and joint pain may manifest as increased irritability, guarding of involved joints, or refusal to walk. Fatigue and low-grade fever, anorexia, weight loss, and failure to grow are other symptoms. Patients with JIA are categorized as having one of the following seven types of disease as established by the International League of Associations for Rheumatology (ILAR): (1) systemic, (2) oligoarthritis, (3) polyarthritis RF+, (4) polyarthritis RF−,

(5) psoriatic, (6) enthesitis-related, and (7) undifferentiated (patients who do not fulfill criteria of other JIA subsets).[201] For a catalog of JIA images, including radiography and ophthalmologic photographs, please go to **http://images.rheumatology.org/search.php?searchField=ALL&searchstring=JIA**.

The most common type of JIA is oligoarthritis, which comprises about 50% to 60% of all JIA cases. This type of JIA typically presents before the age of 6 years, with 80% cases afflicting girls. Oligoarthritis patients present with four or fewer affected joints, most commonly in the ankles. Those who do not progress beyond four joints are categorized with persistent oligoarthritis, but 50% may eventually develop arthritis in additional joints requiring a change in disease classification to extended oligoarthritis.[198,201]

JIA is classified as a polyarthritis when the disease involves five or more joints during the first 6 months of the disease with few or no systemic manifestations of disease.[201] Polyarthritis may be RF+ or RF− and accounts for up to 40% of all JIA disease, the majority of which is RF−.[202] Both types affect girls more often than boys. Disease onset is typically seen at age 8 or older, and most often in adolescents. RF+ polyarthritis presents very similarly to adult-onset RA, involving aggressive, erosive, and symmetric joint inflammation which may lead to general growth retardation, as well as fatigue, morning stiffness, and elevated inflammatory markers.[196,198]

Psoriatic JIA accounts for a small number of all JIA cases (about 5%) and is diagnosed if chronic arthritis and psoriasis are both evident. Children may also be diagnosed with psoriatic JIA if any two of the following are present: dactylitis (finger or toe inflammation), onycholysis or nail pitting, or family history of psoriasis.[196,201]

Enthesitis-related JIA is manifested as inflammation of the enthesis (the site of attachment of tendon to bone) along with arthritis, typically in the lower limbs, in boys older than 6 years old. Children with enthesitis-related JIA have at least two of the following in addition to arthritis or enthesitis: inflammatory lumbosacral or sacroiliac joint pain, HLA-B27 positivity, symptomatic anterior uveitis, or a family history of enthesitis-related JIA or ankylosing spondylitis (first-degree relative).[201,203]

CASE 44-11

QUESTION 1: J.R., a 4-year-old girl, is brought to the hospital for high fever and arthritis. Several weeks before admission, J.R. had a daily fever ranging from 103°F to 106°F. One week before admission, her knees became painful and swollen. J.R. is listless and irritable during her physical examination, and her rectal temperature measures 102.4°F. She refuses to walk. The right hip is tender, and the right wrist and both knees are warm, red, and swollen. Minimal generalized lymphadenopathy and splenomegaly are present. The Westergren ESR is 82 mm/hour, the white blood cell count is 37,000 cells/μL with a mild left shift, and hematocrit is 33%. Cultures of the throat, urine, stool, and blood are negative. MD global assessment is 4. An intermediate-strength purified-protein derivative, antistreptolysin-O titer, ANA titer, and RF titer are normal, as are radiographs of the chest and involved joints. An electrocardiogram reveals only tachycardia. After withholding aspirin, an evanescent rash becomes apparent in conjunction with fever spikes. What signs and symptoms of JIA does J.R. manifest?

The last category of JIA is systemic JIA, which is distinguished from other forms of the disease by the presence of hallmark systemic features including rash, lymphadenopathy, hepatomegaly or splenomegaly, serositis and cyclical high-spiking fever. J.R. exhibits these distinguishing symptoms and, in addition she also experiences joint pain in her knees, with other commonly afflicted joints including the wrists and ankles. The pain often worsens when fever is elevated, but may not be clinically evident at disease onset. Systemic JIA occurs equally in girls and boys and comprises approximately 15% of all JIA cases. Children presenting with this subtype of JIA may also have a normocytic, hypochromic anemia, elevated ESR, and thrombocytosis. Leukocytosis is common, and a white blood cell count of 30,000 to 50,000 cells/µL is seen occasionally. A positive RF titer is uncommon in JIA and is present in only 5% to 10% of all cases.[197,198]

Prognosis

CASE 44-11, QUESTION 2: What is the expected prognosis for J.R.?

Features of poor prognosis for patients with JIA generally include arthritides that involve cervical spine or hip joints, involvement of the ankle or wrist coupled with significant or prolonged elevation of ESR or other inflammatory markers, and radiographic damage.[199] Disease remission is qualified by lack of active arthritis in joints, absence of systemic symptoms (rash, fever, lymphadenopathy, etc.), symptomatic uveitis not present, normal ESR or CRP, and no disease activity measured on a physician's global assessment scale. While only 5% of patients achieve true remission, sustained periods of good control is becoming more common with treatment advances, and up to 35% to 50% of patients achieve clinical remission on medication therapy. Despite improvements in care, complete remission is still uncommon, and up to one-third of patients with JIA do experience long-term disability and decreased quality of life. Preservation of joint function is least promising in children with RF+ polyarthritis.[204–206] Although J.R. is exhibiting some poor prognostic indicators (hip and wrist involvement, elevated ESR), it is unclear whether these are long-term manifestations. Normal ANA and RF titers and the absence of radiographic damage are favorable for J.R.

Treatment

The goals of JIA treatment are to minimize joint inflammation and its destructive effects, control pain, preserve or restore ROM, facilitate an acceptable quality of life, and achieve long-term disease remission. Choice of medication therapy requires consideration of type of JIA, current treatment, degree of disease progression, level of disease activity, and prognosis.[199]

NONPHARMACOLOGIC THERAPY

In addition to treatment with medication, many patients with JIA can benefit from nonpharmacologic efforts to help preserve joint flexibility, maintain ROM, and prevent disability in adulthood. Patients with JIA are often less physically active and more easily fatigued than their disease-free peers, and they may meet developmental milestones later than children of the same age.[207] Children with JIA are also more prone to decreased bone mineral density than their peers.

CASE 44-11, QUESTION 3: J.R.'s parents understand the need for medication therapy but also want to encourage lifestyle interventions as a way to promote health and combat disease complications. What recommendation can the physician give to J.R. and her family once her acute symptoms are stabilized?

Heat and cold therapy, massage, and regular physical activity can all help reach disease treatment goals of minimizing joint inflammation, controlling pain, and improving quality of life. Regular physical activities, including muscle-strengthening, ROM activities, stretching, and endurance training, are safe and do not worsen arthritis. Weight-bearing exercise can help prevent bone loss, but it should be avoided when joints are acutely inflamed. At these times, low-impact sports such as swimming or bicycling can be enjoyed. Physical therapy and occupational therapy can also help pediatric patients hone gross and fine motor skills, balance, and coordination.[207,208] Once J.R.'s status improves, she should be encouraged to participate in regular exercise and organized therapy sessions to improve exercise capacity and preserve joint functioning.

PHARMACOLOGIC THERAPY AND TREATMENT CONSIDERATIONS

While ILAR differentiates JIA into seven disease types, the ACR treatment recommendations classify treatment groups by a different system, since there is little evidence to support pharmacologic decisions based on disease categorization itself. The five treatment groups consist of (1) history of arthritis in four or fewer joints, (2) history of arthritis in five or more joints, (3) active sacroiliac arthritis, (4) systemic arthritis without active arthritis, and (5) systemic arthritis without active arthritis.[199] However, the 2013 ACR update on systemic arthritis subdivides this treatment category into three distinct clinical phenotypes: (1) with active systemic features and varying degrees of synovitis, (2) without active systemic features and with varying degrees of active synovitis, and (3) features concerning for macrophage activation syndrome (MAS).

The history of arthritis of four or fewer joints treatment group includes ILAR disease-classified patients with extended oligoarthritis, RF− polyarthritis, RF+

polyarthritis, psoriatic arthritis, enthesitis-related arthritis, and undifferentiated arthritis, all have had no more than four affected joints in their disease course. NSAIDs as monotherapy may be initially considered for those with low disease activity; however, step-up therapy includes intra-articular glucocorticoid injections followed by methotrexate, and finally TNF-α inhibitors in those with poor response. NSAIDs can always be used as adjunctive therapy for any patient with JIA; however, it should never exceed 2 months as monotherapy without addition of other treatment. Triamcinolone hexacetonide is the intra-articular glucocorticoid of choice and can provide clinical improvement for a minimum of 4 months; step-up to csDMARD therapy may be warranted if symptoms are not controlled within this period.[209,210] MTX may be initiated in those who either fail initial therapy with NSAIDs and intra-articular injections or in those who have high disease activity and poor prognosis. In those with enthesitis-related JIA specifically, SSZ is the initial csDMARD over MTX because of evidence of improved clinical symptoms and long-term outcomes.[203] Finally, in those who still lack response after 3 to 6 months of optimized MTX therapy, TNF-α inhibitors may be initiated. Since publication of the ACR treatment recommendations, tocilizumab has been approved for polyarticular JIA. While place in therapy is not specified except for systemic JIA, it may be alone or in combination with methotrexate as step-up from initial therapy.[57]

Patients who experience arthritis of five or more joints in the duration of disease course should have MTX considered as first-line therapy. The role of NSAIDs is de-emphasized in this treatment group; patients may undergo a short 1- to 2-month course, but quick escalation to DMARD therapy is cornerstone in order to slow disease progression. Because of extensive experience with LEF, this agent may be considered as an alternative to MTX or in those with high disease activity and poor prognosis. For those who fail DMARD therapy after 3 to 6 months, a TNF-α inhibitor may be initiated, followed by switch to another TNF-α inhibitor or abatacept if response remains poor after 4 months of initial bDMARD therapy. For those who fail both TNF-α inhibitor and abatacept, rituximab is the last-line bDMARD agent.

Patients with active sacroiliac arthritis may include individuals from any of the JIA disease categories, but the treatment group must be defined by both clinical and imaging evidence of the disease. Step-up therapy quickly intensifies to TNF-α inhibitors following failed trials of optimized NSAID or csDMARD (MTX or SSZ).[199]

Systemic JIA is subdivided into three treatment categories based on clinical phenotype. In those without active systemic features, NSAIDs can be used as monotherapy initially but should be reserved for those with low disease activity and should not be continued as sole therapy for longer than 2 months. If four or fewer joints are involved, injectable glucocorticoids may be considered

---

concurrently, but if five or more joints are impacted, favor should be placed on either MTX or LEF over injectable glucocorticoid. Following treatment failure of csDMARD, several bDMARDs including abatacept, anakinra, and tocilizumab may be considered.

About 10% of pediatric patients with JIA develop MAS, a life-threatening complication characterized by fever, pancytopenia, liver insufficiency, and coagulopathy among others and if hospitalized, it is associated with a 6% mortality rate. In these patients, anakinra, calcineurin inhibitors, and systemic glucocorticoid therapy should be considered.[197]

CASE 44-11, QUESTION 4: Are NSAIDS an appropriate choice for initial drug therapy for the treatment of systemic JIA in patient J.R.?

NSAID therapy may be considered as first-line treatment for 1 to 2 months in most cases of oligoarticular and polyarticular JIA.[199] However, the use of NSAIDs as monotherapy beyond 2 months in patients with active arthritis is not recommended, regardless of the presence of poor prognostics features.[199] In the case of systemic JIA, as with patient J.R., NSAIDs may be considered as monotherapy in patients with JIA with an MD global <5 and any level of joint involvement. However, therapy should be stepped up in patients with continued disease activity after 1 month on NSAID monotherapy.[197] NSAIDs are useful in systemic JIA as they target joint inflammation as well as the febrile episodes common in systemic JIA.[198,211] These medications work to control pain, fever, and inflammation by inhibiting prostaglandin synthesis and are usually fairly well tolerated by children. Analgesic effects usually occur first, and with continued use NSAIDs' anti-inflammatory effects will begin within a few weeks.

Many of the traditional NSAIDS as well as celecoxib have been used to treat JIA. The most commonly prescribed NSAIDs for JIA are naproxen and ibuprofen. Naproxen is approved for the treatment of JIA in patients ≥2 years old at a dose of 5 mg/kg by mouth twice daily and is advantageous in school-age children because of the convenient dosing interval and availability in liquid or tablet formulations.[211] Ibuprofen is indicated for the treatment of JIA in patients aged ≥1 years old. For patients from 1 to 12 years, ibuprofen is recommended at a dose of 30 to 40 mg/kg/day given in three or four divided doses. Ibuprofen is also available in tablet and liquid formulations.[212]

In most cases, at least two different NSAIDs should be tried before ruling out this group of medications owing to lack of efficacy or tolerability.[213] Failure to respond to an NSAID in a particular chemical class does not rule out the efficacy of others in the same class. As with adults, it is not possible to predict a pediatric patient's response to any one NSAID.

Given the presence of active systemic features (fever, lymphadenopathy, splenomegaly, and evanescent rash) along with an MD global of <5 and AJC of 4 (right hip, left and right knees, right wrist), either an NSAID or anakinra would be the appropriate first-line agents for J.R.[197] Either ibuprofen or naproxen would be sensible first choices. Ibuprofen is available over-the-counter in liquid and chewable forms, which is an important consideration for a 4-year-old. Naproxen is also available in an oral liquid suspension by prescription and can also be considered as initial therapy.

CORTICOSTEROIDS

CASE 44-11, QUESTION 5: J.R., who weighs 33 lb, was prescribed Naproxen 125 mg/5mL oral suspension at a dose of 75 mg BID. Her parents have given her the medication twice daily as directed for the past 4 weeks, but she continues to have disease activity with persistent fever. What should the next step in therapy be for J.R.?

It is inappropriate to continue NSAID monotherapy in a patient who continues to have disease activity after 1 month of treatment. Therefore, alternate treatment options should be explored. The ACR guidelines recommend the use of systemic glucocorticoid therapy in patients with systemic JIA, but not in patients with nonsystemic JIA.[199]

Despite the potential for serious adverse effects associated with high-dose or long-term therapy, the use of low-dose corticosteroids is sometimes necessary to control disease flares or provide therapeutic relief during initiation of DMARDs with slow onsets of action. Systemic glucocorticoids may be considered as adjunctive therapy for systemic JIA at any point in treatment.[197]

It is preferable that patients take the lowest effective corticosteroid dose for the shortest duration possible to avoid long-term side effects such as hypertension and osteoporosis. Oral corticosteroids are typically dosed once daily in the morning to best mimic physiologic cortisol release and minimize suppression of the hypothalamic–pituitary–adrenal axis. For J.R., systemic glucocorticoids are an appropriate next step in therapy and may be considered as adjunctive therapy, if necessary, throughout the course of her disease.

CASE 44-11, QUESTION 6: What corticosteroid side effects should J.R. be counseled about?

Common side effects of steroids include GI upset and damage to the GI mucosa, mood changes including depression or hyperactivity, and increases in blood pressure and blood sugar.[212] Corticosteroids may also cause impaired skin healing, osteoporosis (especially with long-term use), and vision problems such as cataracts and glaucoma. J.R.'s parents should be counseled about receiving vaccinations during corticosteroid therapy because immunosuppression may attenuate an appropriate immune response. Inactivated vaccines are safe for use in immunocompromised patients and should be administered if indicated.[212] Immunocompromised patients typically have a weaker immune response to vaccines when compared with healthy patients; therefore, higher doses or more frequent revaccinations may be necessary.

Greater caution must be taken with live-virus vaccines in immunosuppressed patients. The risk of immunosuppression in patients receiving corticosteroids is dependent on corticosteroid dose, duration, and route of administration; local corticosteroid treatments (e.g., topical, inhalation, and intra-articular) do not put patients at risk.[214] Patients receiving short-term corticosteroid therapy (i.e., <2 weeks), every-other-day dosing with a short-acting corticosteroid, or doses of no more than moderate range can usually receive live-virus vaccines. Corticosteroid dosing that is considered high risk for immunosuppression is the equivalent of at least prednisone 2 mg/kg/day or 20 mg/day; patients receiving corticosteroid dose equivalents in this range should not receive live-virus vaccines. Patients receiving high-dose corticosteroids systemically for 2 or more weeks should wait at least 3 months before receiving a live-virus vaccine.[214]

Intra-Articular Corticosteroid Therapy

CASE 44-11, QUESTION 7: J.R.'s pain in both knees has continued to limit to her willingness to walk. Her parents are concerned about her lack of activity and would like to know if there are any options for relieving her pain more quickly. Would intrarticular glucocorticoid therapy be an appropriate option for reducing knee pain in J.R.?

Intra-articular corticosteroid therapy seems to be highly effective in JIA. Injections are typically reserved for patients who have not responded to conventional NSAID therapy or who present with monoarthritis or oligoarthritis, and current guidelines

suggest they are recommended for all patients with JIA having active disease in four or fewer joints, regardless of activity level, prognosis, or joint deformity.[199] Intra-articular steroid injections are also recommended as adjunct therapy in other forms of JIA, including patients with active disease in five or more joints and those with systemic JIA. Compared with NSAIDs, steroid injections are much better able to reduce duration of joint pain.[213] Full disease remission of injected joints lasting longer than 6 months can be expected in more than 80% of patients with JIA, and 60% of patients may be able to discontinue all oral medications with lasting disease remission in treated joints.[215] In one study, after an average of 30 months of follow-up, long-term negative effects of corticosteroid therapy (e.g., joint stability, osteonecrosis, and soft tissue atrophy) were not encountered. As a result, intra-articular corticosteroid therapy seems to be a safe and effective option for JIA, particularly in oligoarticular disease limited to a few joints.[198]

Intra-articular steroid injections would be appropriate adjunctive treatment for J.R. Her parents should be advised to limit her activity for a couple of days after the injection, but she should be encouraged to resume normal activity and physical therapy to maintain joint flexibility and ROM soon after the treatment.[213] Repeated intra-articular injections are usually given several months apart. Side effects include local lipoatrophy or articular calcification, both of which do not present many issues clinically.

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

CASE 44-11, QUESTION 8: After 2 weeks of glucocorticoid monotherapy, J.R. continues to have moderate disease activity. Her doctor would like to start DMARD therapy, but it is uncertain whether a csDMARD or bDMARD would be preferred. What would you recommend?

Early csDMARD therapy should be considered for patients with history of arthritis of four or fewer joints (e.g., persistent oligoarthritis) as well as patients with history of arthritis of five or more joints (e.g., extended oligoarthritis and polyarthritis [RF positive and RF negative]).[199] MTX is the DMARD of choice for these forms of JIA. For systemic JIA, MTX or leflunomide should be considered first-line in patients without systemic features and AJC > 4 and as second-line therapy and beyond for any number of active joints. MTX or leflunomide may also be considered for systemic JIA as second-line therapy and beyond for patients with systemic features. However, csDMARDs have not been shown to be as effective against systemic JIA as compared to other forms of JIA.[216,217] For a patient like J.R. with systemic JIA with active systemic features, MTX or lefluonomide could be considered, but given relative lack of efficacy, other options, including several of the bDMARDs, are preferred.

Biologic Agents

CASE 44-11, QUESTION 9: Given that csDMARDs would not be an optimal treatment option for J.R., which of the bDMARDs would be most appropriate for treating systemic JIA in J.R.?

There are currently four FDA-approved biologic agents available to treat forms of JIA: etanercept, adalimumab, and abatacept for JIA and canakinumab for systemic JIA. There are also several bDMARDs which are not FDA-approved for the treatment of JIA but are recommended in the ACR guidelines including anakinra, rilonacept, rituximab, the TNF-α inhibitors as a class, and tocilizumab.[197] While the TNF-α inhibitors have demonstrated excellent efficacy in the treatment of adult RA as well as polyarticular JIA, they have not shown similar efficacy in the treatment of systemic JIA. The exact pathophysiology of systemic JIA remains unclear, but the pro-inflammatory cytokines IL-1 and IL-6 have been identified as targets of pharmacotherapy.[197,217–219] Thus, IL-1 inhibitors anakinra, canakinumab, and rilonacept as well as IL-6 inhibitor, tocilizumab, have demonstrated efficacy in the treatment of systemic JIA, and their use is addressed in the ACR treatment guidelines.[197]

IL-1 inhibitors, anakinra and canakinumab, are recommended for the treatment of systemic JIA, while rilonacept's place in therapy remains unclear. Anakinra blocks the action of IL-1α and IL-1β by inhibiting IL-1 binding to the interleukin-1 type receptor (IL-1R1). While anakinra has shown suboptimal efficacy in the treatment of adult RA, patients with systemic JIA have responded well to anakinra treatment. Case reports of good response to anakinra in patients who were refractory to other treatments for systemic JIA led to increased use of anakinra in patients with systemic JIA.[217,217,220] In a small randomized, controlled trial in patients with systemic JIA, 8 out of 12 patients in the anakinra group achieved the primary outcome (30% improvement in clinical status, resolution of fever, and 50% decrease or normalization of both CRP and ESR) versus 1 out of 12 patients in the control group. Furthermore, 10 of the patients in the control group were switched to anakinra after 1 month and nine of these patients also responded to anakinra treatment.[220] While anakinra is not FDA-approved for JIA, the dose that has been used in clinical trials is 2 mg/kg subcutaneously daily, with a maximum daily dose of 100 mg.[220] As with all of the bDMARDs, patients should be monitored for increased risk of infection when taking anakinra. Anakinra would be an appropriate treatment for J.R. following lack of response to NSAID and glucocorticoid monotherapies.

Canakinumab is a human monoclonal antibody, which binds IL-1β and blocks its interaction with IL-1 receptors. It is FDA-approved for the treatment of systemic JIA at a dose of 4 mg/kg subcutaneously every 4 weeks for patients with a body weight of ≥7.5 kg (maximum dose 300 mg).[221] In a randomized, placebo-controlled trial evaluating canakinumab for the treatment of systemic JIA, 84% of subjects experienced a 30% clinical response in the canakinumab group compared to only 10% in the placebo group ($p < 0.001$) 15 days after one dose of canakinumab.[222] In another trial in patients receiving open-label canakinumab for 32 weeks, there was a significantly lower risk of flares in the canakinumab patients and the average glucocorticoid dose was reduced in the canakinumab group.[222] Canakinumab, like other bDMARDs, has been associated with increased risk of infections. It has also been associated with MAS. This association may be attributed to the severity of the disease in patients treated with canakinumab and a causal relationship has not been established.[222] Canakinumab would also be an appropriate treatment option for J.R. The monthly dosing may be preferred over the daily dosing required with anakinra.

Rilonacept is an interleukin 1 inhibitor that binds IL-1β as well as IL-1α and IL-1 receptor antagonist with lesser affinity.[223] While rilonacept has demonstrated efficacy for the treatment of systemic JIA, its place in therapy remains unclear.[224] It should not be used as first-line therapy, and its use for continued disease activity was considered uncertain according to the ACR guidelines.[197]

Tocilizumab is a monoclonal antibody against the IL-6 receptor. It is recommended for patients with systemic JIA with active systemic disease and continued disease activity following a trial of glucocorticoid monotherapy, csDMARD, or anakinra.[197] It is also recommended in systemic JIA patients without systemic features who have an AJC > 0 following treatment with anakinra or a csDMARD.[197] The TCZ dose used in clinic trials for systemic JIA is 8 mg/kg for weight ≥30 kg or 12 mg/kg for weight <30 kg given intravenously every 2 weeks.[225] In a randomized trial of tocilizumab for systemic JIA, 71% of children who received TCZ experienced a 70% improvement in clinic status, compared to 8%

---

of patients who received placebo.[227] Like canakinumab, there has been an association between TCZ and MAS, while anakinra has been shown to be effective in the treatment of MAS.[217]

Patient J.R. has tried an NSAID and systemic glucocorticoid, but she continues to have active systemic RA. Anakinra, canakinumab, and tocilizumab would all be appropriate treatment options for J.R. Canakinumab is FDA-approved for systemic JIA and has the most convenient dosing regimen of these three options. Therefore, canakinumab would be the best option for J.R.

CASE 44-12

QUESTION 1: Seven-year-old C.E. has polyarthritis that consistently has not responded to NSAID or MTX therapy. Given the many potential side effects, C.E.'s parents are concerned about her taking steroids and refuse to let their daughter take them. They are worried about permanent joint damage and wish to try a biologic agent in hopes of finally suppressing disease activity. They have heard that biologic drugs are "safer than steroids" and want to know which agents are available to treat JIA in C.E.

There are three FDA-approved biologic agents available to treat JIA: etanercept, adalimumab, and abatacept. As discussed in the previous section, canakinumab is approved for the treatment of systemic JIA.

Etanercept is a recombinant TNF-receptor Fc fusion protein indicated for patients 2 years of age with polyarticular JIA. ETA is recommended for patients with oligoarticular or polyarticular JIA, who continue to have active RA despite 3 months of treatment with MTX at the maximum tolerated dosage.[199] The recommended dose is 0.8 mg/kg (maximum 50 mg) subcutaneously weekly.[44] The safety of etanercept in children is comparable to adults with the exception of significantly more abdominal pain (17% of patients with JIA vs. 5% of adult patients with RA) and vomiting (14.5% of patients with JIA vs. <3% of adult patients with RA). Patients with JIA should be up-to-date on their immunizations before initiation of etanercept therapy because the effect of etanercept on vaccine response is unknown. Safety and efficacy data reflecting up to 10 years of treatment support the long-term use of etanercept for JIA.[226]

Adalimumab is a human monoclonal TNF-α antibody approved for use in patients aged 2 years of age and older with moderately to severely active polyarticular JIA.[45] It is a weight-based dose (10 mg for patients 10 to <15 kg, 20 mg for patients 15 to <30 kg, 40 mg for patients ≥30 kg) given as a subcutaneous injection every other week.[45] In a study involving 171 patients on adalimumab monotherapy and in combination with MTX, children taking combination therapy showed better disease improvement than patients on adalimumab monotherapy.[45] Concomitant steroids, salicylates, NSAIDs, or other analgesic agents may also be continued during adalimumab use.

Abatacept is an injectable biologic agent that inhibits T-cell activation. This drug received approval for JIA in 2008 and is indicated for use in patients 6 years and older with moderate to severe active polyarticular juvenile idiopathic arthritis. Patients weighing less than 75 kg receive a dose of 10 mg/kg via IV infusion for 30 minutes, while patients weighing 75 kg or more should receive the adult intravenous regimen, with a maximum dose of 1,000 mg.[52] All patients receive doses at 2 and 4 weeks after the first infusion and then every 4 weeks thereafter.[52] Unlike TNF-α agents, abatacept does not have an immediate onset and seems to exert its effect best after repeated doses over the course of several months.[213]

Other biologic agents, including the other TNF-α inhibitors, are not FDA-approved for JIA but have been studied. Available data from clinical trials suggest that all of these treatments may be safe and effective for JIA with no evidence of significant risk for serious adverse reactions. Owing to their mechanisms of action, all biologic agents share the side effect of lowered infection resistance, and patients must be monitored for signs of infection during treatment.

Of all FDA-approved bDMARDs, C.E. is a candidate for etanercept, adalimumab, or abatacept therapy. Given that abatacept does not have an immediate onset, etanercept or adalimumab may be preferred. Adalimumab with its biweekly dosing schedule may be preferred compared to weekly dosing with etanercept. C.E. will also be able to continue her concurrent NSAID and MTX therapies during adalimumab treatment, because it is possible she will experience enhanced clinical improvement on combination therapy versus adalimumab alone.

CASE 44-13

QUESTION 1: T.T. presents to rheumatology clinic on referral from her primary-care provider. She is 9 years old and has been complaining at home of her shoes hurting her feet and not being able to run with her classmates at school. On physical examination it is noted she has multiple swollen, erythematous joints (tarsometatarsal and metatarsocuneiform joints bilaterally on the feet, ankles bilaterally, knees bilaterally). Her CBC values are all normal, her ESR is normal, and her RF is positive. In addition to NSAID and steroid therapy, the rheumatologist would like to start a DMARD agent. What DMARD options are available to treat T.T.'s JIA?

Patients with both RF+ polyarthritis and early-onset JIA have poor prognosis in terms of long-term joint function and should receive early consideration for DMARD therapy. MTX is the DMARD of choice for polyarthritic JIA.[227] T.T. is showing classic signs of RF+ polyarthritis and it would be appropriate to choose MTX as a first-line agent for her therapy. The recommended dose of MTX for JIA treatment is 10 mg/m^2 orally or subcutaneously each week. Food reduces the bioavailability of MTX, so MTX should be administered on an empty stomach. Radiologic evidence of improvement or slowing of joint damage has been demonstrated in patients with JIA who responded to MTX therapy during a 2-year period.[228] Other DMARD options for JIA include leflunomide, sulfasalazine, or hydroxychloroquine. MTX is favored over these alternate csDMARDs and leflonomide is the preferred second-line csDMARD.[199]

CASE 44-13, QUESTION 2: What is the expected response to MTX treatment for T.T.?

The likelihood of long-term or permanent JIA-related joint damage is less than that associated with adult RA; therefore, discontinuation of MTX should be attempted when disease remission is apparent. The optimal time to discontinue MTX therapy remains unknown; however, it probably should not be stopped sooner than 1 year after disease remission, with slower withdrawal in patients at high risk for relapse.[229,230]Young age at diagnosis (<4.5 years) and oligoarthritis that progresses to polyarthritis seem to be the greatest risk factors for relapse.[229,231]

Children tolerate MTX therapy well and generally experience few serious or troublesome adverse effects (e.g., transient liver enzyme elevations, nausea, vomiting, and oral ulcerations).[230] These adverse effects are reduced with daily folic acid therapy (1 mg) or weekly folinic acid (the day after MTX dosing). Liver toxicity monitoring in JIA is the same as the guidelines recommend for MTX therapy in adult RA, including biopsy recommendations. The combination therapy of MTX and other DMARDs has not been fully evaluated in pediatric patients.

Gout and Hyperuricemia

Kimberly Ference and KarenBeth H. Bohan

	CORE PRINCIPLES	CHAPTER CASES
1	Gout is a disease that causes acute joint inflammation and pain secondary to the deposition of monosodium urate (MSU) crystals within the synovial fluid and lining. Clinically, acute gout presents as monoarticular inflammation in 85% to 90% of patients with the first metatarsophalangeal joint (great toe) typically affected; this is called podagra. Patients presenting with acute gout may or may not have hyperuricemia.	**Case 45-1 (Question 1), Table 45-1**
2	A definitive diagnosis of gout can be made if MSU crystals are present in a synovial fluid sample. However, this is rarely done in clinical practice, and other diagnostic criteria are available.	**Case 45-2 (Questions 1–3), Table 45-1**
3	The primary goal of treating acute gout attacks is the relief of pain and inflammation. It is not necessary to lower the serum uric acid (SUA) immediately.	**Case 45-2 (Question 3), Table 45-3**
4	Acute episodes of gout are primarily treated with nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, or corticosteroids.	**Case 45-2 (Questions 4, 5), Case 45-3 (Question 1), Table 45-3**
5	Low-dose oral colchicine is as effective as and safer than traditional high-dose regimens, which are dosed to toxicity (diarrhea); Avoid potential colchicine drug–drug interactions.	**Case 45-2 (Questions 4, 5), Case 45-3 (Questions 1, 5), Table 45-3**
6	Nonpharmacologic therapy for acute and chronic gout includes limiting daily alcoholic beverages, purine-rich meats, and fructose-containing beverages/foods. Specifically, beer and, to a smaller extent, spirits are associated with increased gout attacks; wine is less likely to be a risk factor. Increasing low-fat dairy protein has a favorable effect on SUA.	**Case 45-1 (Question 3), Case 45-2 (Question 6), Table 45-3**
7	Urate-lowering therapy (ULT) should not be initiated or discontinued during treatment for an acute gout attack. Chronic ULT should be started only if the patient has two or more gout episodes in 1 year or the patient has comorbidities such as renal failure, uric acid stones, or urate tophi.	**Case 45-3 (Questions 2, 3), Table 45-3**
8	Patients should be evaluated for drug-induced hyperuricemia before treatment.	**Case 45-3 (Question 3), Table 45-3**

9	The goal of ULT is to lower the SUA to less than 6 mg/dL. If this goal is achieved, most patients can be “cured” of acute gout attacks.	**Case 45-3 (Questions 3–5), Table 45-3**
10	The preferred first-line treatment of gout and hyperuricemia is xanthine oxidase (XO) inhibitors. Monitor for drug–drug interactions.	**Case 45-3 (Questions 4, 5), Tables 45-3**
11	Initiation of ULT can precipitate acute gout attacks, so prophylaxis with either colchicine or NSAIDs is recommended and should be continued for 6 months.	**Case 45-3 (Question 5), Table 45-3**

PATHOPHYSIOLOGY

Gout is a disease that most commonly manifests as recurrent episodes of acute joint pain and inflammation secondary to the deposition of monosodium urate (MSU) crystals in the synovial fluid and lining. MSU deposition in the urinary tract can cause urolithiasis and urinary obstruction.[1] Patients with gout cycle between flares of acute joint pain and inflammation and intercritical gout (i.e., periods of quiescence with no symptoms of the disease). In addition, they can also exhibit chronic tophaceous gout and hyperuricemia.

Tophi are hard nodules of MSU crystals that have deposited in soft tissues and are most commonly found in the toes, fingers, and elbows. Although gout is often associated with hyperuricemia (defined as a serum urate level of greater than or equal to 6.8 mg per deciliter)[2], elevated serum uric acid (SUA) is not a prerequisite for this painful condition.[3] In a retrospective review of two studies on gout, 14% of patients presenting with acute symptoms had a normal SUA concentration less than 6 mg/dL and 32% had an SUA concentration less than 8 mg/dL.[4] Hence, gout should be considered a clinical diagnosis and hyperuricemia a biochemical one. These two terms are not synonymous and are not interchangeable.

Uric Acid Disposition

Uric acid serves no biologic function; it is merely the end product of purine metabolism. Unlike animals, humans lack the enzyme uricase, which degrades uric acid into more soluble products for excretion. As a consequence, uric acid is not metabolized in humans and is primarily excreted renally, although up to one-third of the daily uric acid produced can be eliminated through the gastrointestinal (GI) tract.[5,6] Therefore, increased SUA concentrations arise from an increase in production or a decrease in renal excretion of uric acid, or a combination of the two.

OVERPRODUCTION

Overproduction of uric acid accounts for approximately 10% of gout cases[5,6] and can result from excessive de novo purine synthesis, which is primarily associated with rare genetic enzyme mutation defects, some neoplastic diseases, aggressive cytotoxic chemotherapy (causing tumor lysis syndrome), and certain myeloproliferative disorders. Overproduction of uric acid can also be the result of excessive intake of dietary purines from meat, seafood, dried peas and beans, certain vegetables (e.g., mushrooms, spinach, asparagus), beer, and other alcoholic beverages.[7,8] Fructose consumption (especially soft drinks) has also been linked with increased uric acid levels.[9] Many patients attempt to avoid intake of these foods; however, dietary restrictions are seldom of much benefit (with the exception of avoiding excessive alcohol, yeast, or liver supplements), and patients should feel comfortable in eating modest quantities of meats, seafood, and vegetables.

UNDEREXCRETION

A defect in the renal clearance of uric acid is the main cause of hyperuricemia and gout in about 90% of patients. Uric acid is filtered in the renal glomerulus and is almost completely (98%–100%) reabsorbed in the proximal tubule. Uric acid is then secreted distal to the proximal tubular reabsorption site, and most is reabsorbed again.[3,6] In normal patients, homeostasis between reabsorption and secretion of urate is maintained. However, many factors (e.g., renal impairment, certain drugs, alcohol excess, metabolic syndrome, hypertension [HTN], coronary heart disease [CHD]) can cause this balance to fail, resulting in excess serum concentrations of uric acid and tissue deposition.[5,10]

ACUTE GOUT

Epidemiology

Classically, gout presents during middle age. The onset of gout is uncommon in prepubertal children, premenopausal women, and men younger than 30 years of age. The appearance of gout in these populations should alert the clinician to the possibility of renal parenchymal disease. The risk of gouty arthritis is approximately the same for both men and women at any given SUA concentration; however, many more men are hyperuricemic. For example, men are six times more likely than women to have SUA concentrations greater than 7 mg/dL. Overall, gout occurs as often in postmenopausal elderly women as in men.[11] Emerging evidence suggests the incidence of gout in increasing in the black population.[12]

Clinical Features

CASE 45-1

QUESTION 1: M.D. is an obese 60-year-old woman who has been referred to a medication management clinic by her primary-care physician. She states that her past medical history includes HTN, type 2 diabetes, hyperlipidemia, and gout. M.D. states she was diagnosed with gout 3 months ago when she had a really painful and swollen right big toe. When asked about that episode, M.D. related the following story: "One morning I just woke up and my big toe was swollen, red, and very painful. I couldn't even put weight on it. I had gone to my husband's 50th high school reunion the night before and it was fine then, because we danced all night. I did have a little too much to drink, though, so I thought maybe I had stubbed my toe without realizing it and broke it." What signs and symptoms did M.D. exhibit that are typical of acute gout?

M.D.'s symptoms of severe, acute pain and an obviously inflamed joint are consistent with the usual presentation of gout. Also, M.D.'s age is consistent with the epidemiologic data that are commonly associated with gout.

PAIN

The pain of gout rapidly reaches its maximum within 6 to 12 hours of onset and is usually accompanied by erythema.[13] It is often so severe that patients cannot even tolerate a sheet lying on top of the affected area.

NUMBER AND TYPE OF JOINTS

M.D.'s report of a very painful big toe is typical, because acute gout attacks affect a single joint 85% to 90% of the time, and most often affect a joint of the lower extremity.[6] The first metatarsophalangeal joint (the great toe) is the most commonly affected joint, and the term podagra specifically refers to gout in this joint.

Although initial gout attacks are primarily monoarticular, as many as 39% of the patients in one study experienced polyarticular involvement as their first manifestation of gout.[14] Generally, recurrent attacks are of longer duration than initial attacks, more likely to be polyarticular, and more smoldering in onset.[15]

NOCTURNAL OCCURRENCE

Acute gouty arthritis commonly begins at night. According to the Simkin hypothesis,[16] small amounts of effusion fluid gravitationally enter into degenerative joints of the feet (or other joints) during the day, when most people are busily walking around, and are reabsorbed during the night when the lower extremities are elevated. Thus, the onset of pain in M.D. during the night is typical of gout.

PHYSICAL STRESS

Gout attacks also seem to be more common during episodes of increased physical exercise. Long walks, hikes, golf games, or tight new shoes have historically been associated with the subsequent onset of podagra.[16] The acute episode of toe pain experienced by M.D. after a night of dancing is consistent with the appearance of gout after increased physical exercise.

Risk Factors

CASE 45-1, QUESTION 2: What findings in M.D. place her at risk for gout?

The diagnoses of HTN, type 2 diabetes, hyperlipidemia, and obesity in M.D. have been associated with an increased risk of gout and hyperuricemia.

Common risk factors include alcohol consumption, the use of urate elevating drugs, and certain comorbidities. Conditions associated with an increased risk of hyperuricemia and gout include insulin resistance, obesity, metabolic syndrome, chronic kidney disease, heart failure, organ transplant, history of urolithiasis, and lead intoxication.[2,17]

CORONARY HEART DISEASE

Hyperuricemia is noted to be an independent risk factor for CHD, although it is unlikely to be a primary cause of disease. Several observational studies have shown a link between hyperuricemia and an increase in CHD (e.g., HTN, stroke, heart failure, and ischemic heart disease).[18-21] Researchers continue to study the causality and note that despite the apparent strong relationship, the subject remains controversial. Impaired glucose utilization also has a relationship with hyperuricemia. Because of these close linkages, patients who present with gout and/or hyperuricemia should be monitored closely for the development of CHD and diabetes.

RENAL DYSFUNCTION

Uric acid excretion is decreased in patients with renal dysfunction owing to decreased glomerular filtration, and as a consequence, hyperuricemia is a common finding. The use of xanthine oxidase (XO) in patients with hyperuricemia and chronic kidney disease has been examined in low-quality studies with mixed results. Currently, treating hyperuricemia in patients with renal dysfunction is not recommended unless patients manifest gouty arthritis.[19,22] Appropriate monitoring of renal function in M.D. by obtaining blood urea nitrogen (BUN), serum creatinine (SCr), and electrolytes is important for evaluating her risk factors as well as determining drug doses for treating gout.

CASE 45-1, QUESTION 3: During the medication management clinic visit, M.D. mentions that her doctor said her gout attack could have been caused by drinking too much beer, and she asks you whether this is really true.

ETHANOL CONSUMPTION

Overindulgence of alcohol has been linked to acute gout attacks. Alcohol intake was examined in a prospective cohort of men with new diagnoses of gout from the Health Professionals Follow-Up Study and found that the risk of gout is 2.5-fold in patients who drink two or more beers/day.[23] Ethanol-induced gout or hyperuricemia has been attributed to several mechanisms. M.D.'s episode of overindulgence of beer, possible dehydration from vigorous exercise, and lactic acidemia from muscle energy expenditure made the diagnosis of an acute gout attack the most likely cause of her toe pain and inflammation.

Diagnosis

CASE 45-2

QUESTION 1: E.J., a 52-year-old male school bus driver, reports to the emergency department with the primary complaint of extreme pain in his right elbow. He admits to playing several games of basketball yesterday followed by a few beers with friends. He awoke in the early hours of the morning with a sore and stiff elbow, which he self-medicated with acetaminophen before trying to get back to sleep. He sought medical attention when his pain escalated to the point where he was unable to apply pressure to the area and struggled to move his arm. Pertinent medical history includes the recent diagnosis of HTN and obesity. At visit with his primary-care physician 1 month ago, E.J. was prescribed hydrochlorothiazide 12.5 mg once daily, which is his only medication. He was also encouraged to go on a diet and to increase his exercise. He states that he has no drug or food allergies and is tolerating the antihypertensive well. On physical examination, the right elbow is exquisitely tender and erythematous, and his vital signs are all within normal limits. The elbow is warm to the touch and has moderate swelling. What objective data would be of value in assisting in the diagnosis of E.J.'s elbow pain and inflammation?

JOINT FLUID ASPIRATION

A definitive diagnosis of gout can be established by finding MSU crystals in the aspirated synovial fluid of the affected joint. The absence of MSU crystals in the synovial fluid, however, does not rule out the diagnosis of gout. Although joint fluid aspiration is considered the gold standard for diagnosis of acute gout, it is rarely done in clinical practice. If synovial fluid is aspirated from an inflamed joint, it should also be analyzed for bacteria and a WBC count should be obtained. In gouty arthritis, the WBC count is likely to range from 5,000 to 50,000/L.[3] In septic arthritis, the WBC count of the synovial fluid is usually greater than 50,000/L. E.J.'s physician may consider fluid joint aspiration as a diagnostic measure if E.J. is agreeable and the physician is equipped to conduct the procedure.

LABORATORY TESTS

Because uric acid primarily is excreted renally and renal impairment is a risk factor for gout, the serum concentrations of E.J.'s BUN and SCr should be measured along with an SUA concentration, especially in light of his history of HTN and hydrochlorothiazide therapy. Although infection, in particular septic arthritis, could also present as sudden onset of joint pain and inflammation, it is not likely in this case. An elevated systemic white blood cell (WBC) count may be consistent with infection or gout. If joint infection is of genuine concern, synovial fluid aspiration could differentiate between infection and gout.

RADIOGRAPHY

Radiographic findings of the affected joint are nonspecific and generally characterized by asymmetric soft tissue swelling overlying the involved joint. When gout has been long-standing, bony changes can be noticed on a radiograph, along with calcium deposition and increased density in the areas of soft tissue swelling.[24] Ultrasound and computed tomography are also used for diagnosis with the latter showing early changes compared to a traditional radiography. (See http://www.healthinplainenglish.com/health/musculoskeletal/gout/forexamples.) A radiograph of E.J.'s elbow should be obtained if other musculoskeletal disorders (e.g., bone fracture) are being considered.

PSEUDOGOUT

Deposition of microcrystals (i.e., calcium pyrophosphate, calcium oxalate, calcium hydroxyapatite) into joints can cause acute or chronic arthritis in a manner similar to that caused by MSU deposition.[25] The role of these microcrystals in causing acute synovitis has been greater than previously expected because improved crystallographic technology (e.g., electron microscopy, radiograph diffraction) can differentiate these diagnoses from that of acute gout. Crystal-induced diseases tend to occur in older patients as a result of prior joint disease, especially osteoarthritis (which is generally a disease of the elderly), predisposing them to crystal deposition and acute episodes of joint inflammation. Older adults are also more prone to microcrystal-induced arthritis because these crystals generally accumulate for a long period and must attain a sufficient concentration and size before they precipitate into the synovial fluid and cause inflammation.[26]

CRITERIA FOR DIAGNOSIS

The American College of Rheumatology (ACR) first suggested classification criteria for gout in 1977, which until recently have been commonly used for diagnosis.[27] In 2015, new criteria for the classification of gout were published via a collaboration between ACR and European League Against Rheumatism (EULAR).[28] The new criteria represent the best available evidence and incorporate a multifaceted, objective approach to making a diagnosis. The ACR/EULAR criteria are streamlined into 3 steps. The updated criteria now separate individuals with symptoms of gout undergoing evaluation of joint fluid aspiration from those not undergoing this procedure (Table 45-1).

In order for gout to be considered, a patient must meet the entry criterion (Step 1), which is described as one or more episodes of pain, swelling, or tenderness in a peripheral joint or bursa. If the entry criterion is met, the clinician moves to Step 2. The sufficient criterion described in Step 2 evaluates the presence of MSU crystals from fluid aspiration of the symptomatic joint, bursa, or tophus. If the patient meets the criteria described in Steps 1 and 2, a diagnosis of gout is made. If fluid aspiration is not performed or the results are negative, the clinician moves to the next step. Step 3 examines three different areas consistent with gout: clinical characteristics (i.e., symptoms, timing, clinical evidence of disease), laboratory findings (i.e., SU synovial fluid analysis), and imaging findings (i.e., results consistent with urate disposition, evidence of joint damage). Step 3 utilizes a scoring method for the different characteristics associated with gout, and a diagnosis is made with a score of 8 or greater. A classification calculator can be found at: http://goutclassificationcalculator.auckland.ac.nz/

CASE 45-2, QUESTION 2: Laboratory tests were ordered for E.J., and the results are as follows:

SUA, 10.1 mg/dL
BUN, 10 mg/dL
SCr, 1.0 mg/dL
WBC count, 10.2 × 10^3/μL

A radiograph of his elbow shows soft tissue swelling with no evidence of tophi. Does E.J. have gout?

Additionally, Table 45-2 discusses the EULAR propositions for the diagnosis of gout.[13]

E.J.'s objective and clinical presentation fulfills the ACR/EULAR criteria for diagnosis, highlighted in Table 45-1. He presents with symptoms meeting the entry criterion, however, and does not meet the sufficient criterion because he did not undergo joint aspiration. When using the classification calculator, the final criteria score is 8 [e.g., pattern of joint involvement (1), characteristics of symptoms (3), and serum urate (4)]. A score of 8 is consistent with a gout classification.

Management Guidelines

Gout is one of few rheumatologic diseases that can be treated successfully and even cured in many patients.[29] However, despite the availability of adequate pharmacologic interventions, a survey of rheumatologists and internists in the United States (US) found that drug therapy is often not used based on scientific evidence for both acute and chronic gout.[30] Another survey of US primary-care physicians found that evidence-based treatment recommendations were made in only 52.8% of cases of acute gout and 16.7% of cases of chronic gout.[31] Because these common practices are contrary to current scientific data, the ACR Guidelines for Management of Gout were developed to provide evidence-based recommendations for treatment.[32] Other European guidelines include EULAR and British Society of Rheumatology and British Health Professionals in Rheumatology (BSR/BHPR) Guidelines for the Management of Gout.[33,34] A comparison of recommendations from these guidelines is found in Table 45-3.

Treatment of Acute Gout

GOALS OF THERAPY

CASE 45-2, QUESTION 3: What is the primary goal in the treatment of E.J.'s acute gout attack?

The primary goal in the treatment of an acute attack of gout for E.J. is to relieve his pain and inflammation. Treatment within 24 hours of symptom onset is recommended to rapidly improve patient symptoms. The immediate goal of therapy should not be aimed at decreasing the SUA concentration with urate-lowering therapy (ULT). Gout sufferers are most likely to have been hyperuricemic for several months or years, and it is not necessary to treat the hyperuricemia immediately. Furthermore, a decrease in the SUA concentration at this time might mobilize urate stores and precipitate yet another acute gout attack. However, if the patient is already receiving ULT, it is not necessary to discontinue therapy during an acute attack.[32–34]

DRUG THERAPY OVERVIEW

CASE 45-2, QUESTION 4: What are the pharmacologic options for the treatment of E.J.'s acute pain?

Acute gouty arthritis can be effectively treated in most instances by using monotherapy with one of the following: nonsteroidal anti-inflammatory drug (NSAID), colchicine, or corticosteroids.[32–34] Each therapy has been proven efficacious when compared to placebo; however, to date, there are limited head-to-head comparisons between agents. Treatment should be based on patient preference, previous response or experience with an agent, and patient-specific factors (e.g., comorbidities, current medications, renal or hepatic impairment). Switching to an alternative agent or add-on therapy may be considered in refractory cases. Combination therapy is recommended in severe cases especially those involving multiple joints. Treatment should be continued until patient is asymptomatic (usually 7–10 days).

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are the preferred first-line therapy for the treatment of acute gout according to the ACR, EULAR, and BSR/BHPR guidelines because of their effectiveness and tolerability.[32–34] Although only a few NSAIDs (i.e., naproxen, indomethacin, sulindac) are US Food and Drug Administration (FDA)-approved for the treatment of pain associated with acute gout attacks, most have been studied and experts consider them equally efficacious.[32,34] The choice of NSAID should be determined based on patient-specific factors, and dosing should be consistent with the FDA-approved recommendations for the treatment of acute pain and/or acute gout. GI bleeding or ulceration and inhibition of platelet aggregation are two of the most common serious adverse effects of nonselective NSAIDs. Both compound the risk of bleeding when given concomitantly with anticoagulants (e.g., warfarin). Among the nonselective NSAIDs, ibuprofen is the least likely to cause GI adverse effects and is perhaps the safest nonselective NSAID for use in patients at risk for GI bleeding, whereas piroxicam and indomethacin are among the worst offenders.[35] The selective cyclooxygenase-2 (COX-2) inhibitor NSAIDs are another option in patients at risk for GI bleeding or when taking chronic anticoagulants because they do not inhibit platelets at normal doses. Published data to support efficacy in acute gouty arthritis exist for etoricoxib and lumiracoxib (withdrawn in most countries due to hepatotoxicity), but these drugs are not available in the United States. Despite limited evidence for use, celecoxib and meloxicam are available in the United States with FDA-approved indications for the treatment of acute gout. A Cochrane systematic review compared nonselective NSAIDs to COX-2 inhibitors for the treatment of acute gout pain and found no significant differences in efficacy. However, the review demonstrated increased cardiovascular risk and GI adverse effects with nonselective NSAID use.[36]

Table 45-1

The ACR/EULAR Gout Classification Criteria

	Categories	Score
Step 1: Entry criterion (only apply criteria below to those meeting this entry criterion)	At least 1 episode of swelling, pain, or tenderness in a peripheral joint or bursa	
Step 2: Sufficient criterion (if met, can classify as gout without applying criteria below)	Presence of MSU crystals in a symptomatic joint or bursa (i.e., in synovial fluid) or tophus	
Step 3: Criteria (to be used if sufficient criterion not met)		
Clinical		
Pattern of joint/bursa involvement during symptomatic episode(s) ever[a]	Ankle or mid-foot (as part of monoarticular or oligoarticular episode without involvement of the first metatarsophalangeal joint)	1
	Involvement of the first metatarsophalangeal joint (as part of monoarticular or oligoarticular episode)	2

Characteristics of symptomatic episode(s) ever ■ Erythema overlying affected joint (patient-reported or physician-observed)	One characteristic	1
■ Can’t bear touch or pressure to affected joint	Two characteristics	2
■ Great difficulty with walking or inability to use affected joint	Three characteristics	3
Time course of episode(s) ever		
Presence (ever) of ≥2, irrespective of anti-inflammatory treatment:		
■ Time to maximal pain <24 hours	One typical episode	1
■ Resolution of symptoms in ≤14 days	Recurrent typical episodes	2
■ Complete resolution (to baseline level) between symptomatic episodes		
Clinical evidence of tophus		
Draining or chalklike subcutaneous nodule under transparent skin, often with overlying vascularity, located in typical locations: joints, ears, olecranon bursae, finger pads, tendons (e.g., Achilles)	Present	4
Laboratory		
Serum urate: measured by uricase method		
Ideally should be scored at a time when the patient was not receiving urate-lowering treatment, and it was >4 weeks from the start of an episode (i.e., during intercritical period); if practicable, retest under those conditions	<4 mg/dL (<0.24 mmol/L)[b]	−4
	6–8 mg/dL (0.36–<0.48 mmol/L)	2
	8–<10 mg/dL (0.48–<0.60 mmol/L)	3
	≥10 mg/dL (≥0.60 mmol/L)	4
The highest value irrespective of timing should be scored		
Synovial fluid analysis of a symptomatic (ever) joint or bursa (should be assessed by a trained observer)[c]	MSU negative	−2

Imaging[d]		
Imaging evidence of urate deposition in symptomatic (ever) joint or bursa: ultrasound evidence of double-contour sign[e] or DECT demonstrating urate deposition[f]	Present (either modality)	4
Imaging evidence of gout-related joint damage: conventional radiography of the hands and/or feet demonstrates at least 1 erosion[g]	Present	4

A web-based calculator can be accessed at: http://goutclassificationcalculator.auckland.ac.nz, and through the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) websites.

[a] Symptomatic episodes are periods of symptoms that include any swelling, pain, and/or tenderness in a peripheral joint or bursa.

[b] If serum urate level is <4 mg/dL (<0.24 mmol/L), subtract 4 points; if serum urate level is ≥4–<6 mg/dL (≥0.24–<0.36 mmol/L), score this item as 0.

[c] If polarizing microscopy of synovial fluid from a symptomatic (ever) joint or bursa by a trained examiner fails to show MSU monohydrate crystals, subtract 2 points. If synovial fluid was not assessed, score this item as 0.

[d] If imaging is not available, score these items as 0.

[e] Hyperechoic irregular enhancement over the surface of the hyaline cartilage that is independent of the insonation angle of the ultrasound beam (note: false-positive double-contour sign [artifact] may appear at the cartilage surface but should disappear with a change in the insonation angle of the probe).[31,32]

[f] Presence of color-coded urate at articular or periarticular sites. Images should be acquired using a dual-energy computed tomography (DECT) scanner, with data acquired at 80 kV and 140 kV and analyzed using gout-specific software with a 2-material decomposition algorithm that color-codes urate (33). A positive scan is defined as the presence of color-coded urate at articular or periarticular sites. Nail bed, submillimeter, skin, motion, beam hardening, and vascular artifacts should not be interpreted as DECT evidence of urate deposition (34).

[g] Erosion is defined as a cortical break with sclerotic margin and overhanging edge, excluding distal interphalangeal joints and gull wing appearance.

Table 45-2

EULAR Propositions for Diagnosis of Gout 2006

Proposition		A + B (%)[a]
1	In acute attacks, the rapid development of acute pain, swelling, and tenderness that reaches peak intensity within 6–12 hours, especially with overlying erythema, highly suggests crystal inflammation (although not specific for gout).	93
2	For typical presentations of gout (e.g., recurrent podagra with hyperuricemia), a clinical diagnosis alone is reasonably accurate, but not definitive without crystal confirmation.	100
3	Demonstration of MSU crystals in synovial fluid or a tophus permits a definitive diagnosis of gout.	100
4	A routine search for MSU crystals is recommended in all synovial fluid samples obtained from undiagnosed joints.	87
5	Identification of MSU crystals from asymptomatic joints may allow for definite diagnosis in intercritical gout.	93
6	Gout and sepsis can coexist. When septic arthritis is suspected, synovial fluid should be Gram stained and cultured for bacteria even if MSU crystals are identified.	93
7	Serum uric acid concentrations, although the most important risk factor for gout, do not confirm or exclude gout. Many with hyperuricemia do not develop gout, and SUA concentrations during acute attacks can be normal.	93
8	Renal uric acid excretion should be assessed in selected gout patients, especially those with a family history of young-onset gout, onset of gout at younger than 25 years, or those with renal calculi.	60

9	Although radiographs can be useful for differential diagnosis and can show typical features of chronic gout, they are not useful in confirming the diagnosis of early or acute gout.	93
10	Risk factors for gout and comorbidity should be assessed, including features of the metabolic syndrome (obesity, hyperglycemia, hyperlipidemia, hypertension).	100

[a]A + B (%) is the percentage of fully (A) and strongly (B) recommended, based on EULAR ordinal scale.
EULAR, European League Against Rheumatism; MSU, monosodium urate; SUA, serum uric acid.

Table 45-3

Comparison of ACR, EULAR, and BSR/BHPR Guidelines for Gout

ACR Management of Gout Part 1[17] and Part 2[32]	EULAR Propositions for Gout Management[33]	BSR/BHPR Guidelines for Management of Gout[34]: Summary of Selected Recommendations
Treatment of Acute Gout		
Treat an acute attack within 24 hours of attack with any of the following: oral NSAIDs, colchicine	Treat as soon as possible with oral NSAIDs or colchicine. In the absence of contraindications, an NSAID is a convenient and well-accepted treatment	Treat acute gout with an NSAID, colchicine, or corticosteroid and continue until attack is terminated (1–2 weeks)
NSAIDs or COX-2 is effective at FDA-approved doses for 1 week	NSAIDs are effective at maximum doses	NSAIDs are drug of choice provided no contraindications for use
Use colchicine 1.2 mg, then 0.6 mg 1 hour later. The 0.6 mg once to twice daily until attack subsides	High doses of colchicine cause side effects, and low doses (e.g., 0.5 mg TID) can be sufficient	Use colchicine in doses of 0.5 mg 2–4 times daily
Recommend prednisone 0.5 mg/kg per day for 5–10 days. Intra-articular recommended for acute gout of 1–2 joints	Intra-articular aspiration and injection of a long-acting steroid are effective and safe treatments for an acute attack	Corticosteroids are effective for acute gout in patients who cannot tolerate NSAIDs or are refractory to other therapy: may use intramuscularly, intravenously, or intra-articularly; the latter is highly effective in monoarticular gout
Treatment of Hyperuricemia to Prevent Recurrent Gout		
ULT is indicated in patients with established gouty arthritis and >2 acute attacks per year, tophi, a history of urolithiasis, and CKD (Stage 2 and higher)	ULT is indicated in patients with recurrent acute attacks, arthropathy, tophi, or radiographic changes of gout	Start long-term ULT in uncomplicated gout only if two or more attacks occur per year
Treat to a minimum SUA of <6	The therapeutic goal of ULT (i.e.,	Plasma urate goal is <300 mmol/L

mg/dL, may consider a goal of <5 mg/dL in patients without symptomatic relief at <6 mg/dL. Begin ULT once attack is controlled	SUA less than or equal to the saturation point for MSU of 6 mg/dL) is to promote crystal dissolution and prevent crystal formation	(<5 mg/dL). Start ULT 1–2 weeks after inflammation has resolved
Recommend ULT with a XO inhibitor (allopurinol or febuxostat). Allopurinol should be initiated at 100 mg/d and titrated every 2–5 weeks until target dose reached. May use doses of >300 mg in renal impairment if it is proper education and monitoring	Allopurinol, an appropriate long-term urate-lowering agent, should be initiated at 100 mg/d and increased by 100 mg every 2–4 weeks, if required. The dose must be adjusted in patients with renal impairment. If toxicity occurs, options include other xanthine oxidase (XO) inhibitors, a uricosuric agent, or allopurinol desensitization (if mild rash)	Initial ULT should be allopurinol starting with 50–100 mg/d and increasing by 50–100 mg every few weeks until therapeutic goal of SUA <300 mmol/L to a maximum of 900 mg/d allopurinol (adjust as necessary for renal dysfunction)
Probenecid may be used as a first-line alternative in patients unable to use or intolerant to at least 1 XO inhibitor. Avoid use in patients with a CrCl <50 mL/min	Probenecid can be an alternative to allopurinol in patients with normal renal function, but is relatively contraindicated in patients with urolithiasis	Uricosuric agents should be used only as a second-line drug in those underexcreting urate and in those resistant to or intolerant of allopurinol
Prophylaxis for acute gout is recommended for 6 months. The first-line agent for prophylaxis against acute gout is colchicine or low-dose NSAIDs. Oral corticosteroids are recommended as a second-line agent	Prophylaxis against acute attacks for up to 6 months of initiation of ULT with colchicine (0.5–1 mg/d) or NSAID (with gastroprotection, if indicated)	Prevent gout attacks by giving colchicine 0.5 mg twice daily for up to 6 months; if patient cannot tolerate colchicine, NSAIDs or COX-2 inhibitors can be substituted but limited to 6 weeks
Adjunctive Therapy to Prevent Recurrent Gout		
Patient education on general health, diet, and lifestyle modifications includes limiting daily alcoholic beverages, purine-rich meats, and fructose-containing beverages/foods. Specifically, beer and, to a smaller extent, spirits are associated with increased gout attacks; wine is less likely to be a risk factor. Increasing low-fat dairy protein has a favorable effect on SUA	Optimal treatment of gout requires nonpharmacologic and pharmacologic modalities tailored to specific risk factors (SUA levels, prior attacks); clinical phase of gout; and general risk factors (age, comorbidity, drug interactions)	Dietary management: includes skim milk and yogurt; favors soybeans and vegetable proteins; restricts intake of high-purine food (<200 mg/d); avoids liver, kidneys, shellfish, and yeast extracts; reduces intake of red meat; favors cherries, fresh or preserved
	Patient education and lifestyle modifications (e.g., weight loss if obese, reduced beer, and other alcohol consumption) are important	Alcohol consumption[a]: restrict to <21 units/wk (men) and <14 units/week (women); two 125-mL glasses of wine per day are usually safe; two 25-mL glasses of spirits per day are safer than 1/2 pint of many beers

[a] 1 unit equals 10 mL of pure alcohol, so the number of units per drink depends on its alcohol content; generally, 6 ounces of wine is about 2 units, a 12-ounce beer is 1.5 units, and a 2-ounce shot is about 1.2 units.

BSR/BHPR, British Society for Rheumatology/British Health Professionals in Rheumatology; COX-2, cyclooxygenase-2; CrCl, creatinine clearance; EULAR, European League Against Rheumatism; GI, gastrointestinal; HTN, hypertension; MSU, monosodium urate; NSAID, nonsteroidal anti-inflammatory drug; SUA, serum uric acid; TID, three times daily; ULT, urate-lowering therapy.

The potential adverse cardiovascular effects of NSAIDs are of concern.

Cardiovascular risk associated with NSAID therapy has been known for some time (e.g., myocardial infarction, stroke); however, newer literature highlights the significance of this risk. Two separate cohort trials indicate increased risk of cardiovascular morbidity and mortality in patients using NSAIDs after an acute myocardial infarction. This risk was increased in patients receiving antithrombotic therapy and was observed even with short-term use (0–3 days).[37] In patients with a history of myocardial infarction, proceed with caution when considering NSAID use. NSAIDs can also aggravate HTN, cause renal failure, inhibit diuretic-induced increases in renal sodium excretion,[38–41] and decrease the hypotensive effect of diuretics and other antihypertensive drugs.[42,43] Patients with CHD and renal insufficiency can be treated for a short duration with nonselective NSAIDs, albeit with much caution. The nonselective NSAIDs are safe for patients with stable, controlled HTN when given for only a few days and with close monitoring of blood pressure.

Colchicine

Colchicine has been successfully used to treat acute gout for more than 2,000 years despite little published research supporting its efficacy.[44] By inhibiting microtubule polymerization, it decreases the action of inflammatory mediators such as cytokines and chemokines. Traditionally, colchicine has been dosed as one or two 0.5- to 0.6-mg tablets initially followed by 0.5 to 0.6 mg hourly or every other hour, until joint pain was relieved or GI effects (i.e., diarrhea, nausea, vomiting) intervened. To minimize these significant adverse effects, the EULAR and BSR/BHPR guidelines[33,34] recommend lower doses of 0.5 mg twice to four times daily. However, the AGREE trial[45] compared a lower-dose regimen (1.2 mg to start followed by 0.6 mg in 1 hour) with the traditional dosing and found significantly fewer adverse effects with the lower-dose regimen and similar efficacy. A 2014 systematic review, combining the AGREE trial with a separate randomized trial, found similar results.[46] Although colchicine has been marketed in the United States since 1961, it was never approved by the FDA as safe and effective. The AGREE trial was the basis of the FDA approval of a new registered colchicine product in the United States. The FDA granted brand exclusivity to this product. Consequently, there are no approved generic alternatives available in the United States.[47,48] The approved dosage is 1.2 mg to start followed by 0.6 mg in 1 hour for the treatment of acute gout and 0.6 mg once to twice daily for gout prophylaxis with a maximal dose of 1.2 mg per day for chronic dosing, which is also consistent with the ACR recommendations. Colchicine should be used cautiously in patients with creatinine clearance (CrCl) less than 30 mL/minute and with hepatic impairment.[32] Colchicine has a number of significant drug interactions that inhibit either cytochrome P-450 (CYP) 3A4 or P-glycoprotein.[49] A thorough medication history is essential to assure safe prescribing. Some common medications that interact with colchicine include digoxin, fibric acids, statins, nondihydropyridine calcium channel blockers, erythromycin, and antifungals. A table detailing significant colchicine drug interactions can be found online in Table 45-4. Common adverse effects include nausea, vomiting, and diarrhea.

Corticosteroids

Historically, corticosteroids have been considered second-line therapy due to the potential for serious adverse effects and adrenal suppression when used long-term as well as the risk of rebound pain when abruptly discontinued.[3,50] However, a recent systematic review found prednisolone to be as effective as NSAIDs for reducing pain from acute gout, and no differences in serious adverse events were observed.[36,51] Corticosteroids may be particularly useful for elderly patients or those with renal disease or CHD who cannot tolerate NSAIDs.[3,34,50,51] Corticosteroid adverse effects (e.g., osteoporosis, myopathy, peptic ulcer disease, central nervous system effects, HTN, predisposition to infections) are not likely with short courses of treatment for gout attacks. Glucose intolerance, however, can occur with short-term therapy. If the acute gout episode involves only one or two large joints, intra-articular corticosteroid administration is recommended by the ACR[32], EULAR[33], and BSR/BHPR[34] guidelines, despite limited evidence. There is also evidence to support the use of intramuscular corticosteroids especially for patients unable to take oral medications.[32]

Analgesics

When an occasional patient requires more pain control, a dose or two of nonopioid or opioid analgesics can be a reasonable adjunctive therapy to blunt the pain of acute gouty arthritis while awaiting the apparent benefits of NSAIDs, colchicine, or corticosteroids.[6] Most patients, however, generally experience benefits from NSAIDs, colchicine, and corticosteroids soon after a dose is administered.

Other Agents

Alternative regimens include the use of adrenocorticotropic hormone (ACTH) and interleukin-1 inhibitors (IL-1). The ACR guidelines recommend the use of ACTH drugs, such as corticotropin, as an alternative to IM/IV corticosteroids in patients unable to take oral medications; however, the significant expense may outweigh the benefits of this medication.[32] Interlukin-1 agents (e.g., anakinra, rilonacept, canakinumab) have not been approved by the FDA for the treatment of acute gout. A systematic review comparing canakinumab to intramuscular triamcinolone indicated that canakinumab was more effective in pain reduction during an acute flare; however, it had significantly higher serious and nonserious adverse effects.[52] The ACR guidelines recommend reserving these agents for situations where traditional medications are contraindicated to ineffective until there is a clearer idea of the risk and benefit profile.[32] As with the ACTH medications, the cost of IL-agents may prohibit use.

CHOICE OF AGENT

CASE 45-2, QUESTION 5: What therapeutic intervention would be most appropriate for E.J. at this time?

Table 45-4

Colchicine Drug Interaction

Interacting Drugs	Description
Cobicistat	May increase the return concentration of colchicine. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are also receiving a strong CYP3A4 inhibiter like cobicistat. In those with normal renal and hepatic function, reduce colchicine dose as directed. Consider therapy modification.
Conivaptan	May increase the serum concentration of CYP3A4 substrates. Avoid combination.
Cyanocobalamin	Colchicine may decrease the serum concentration of cyanocobalamin. Monitor therapy.
CYP3A4 inhibitors (moderate)	May increase the serum concentration of colchicine. Management: Reduce colchicine dose as directed when using with a moderate CYP3A4 inhibitor, and increase monitoring for colchicine-related iconicity. Use extra caution in patients with impaired renal and/or hepatic function. Consider therapy modification.
CYP3A4 inhibitors (strong)	May increase the serum concentration of colchicine. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are also receiving a strong CYP3A4 inhibitor. In those with normal renal and hepatic function, reduce colchicine dose as directed. Consider therapy modification.
Dasatinib	May increase the serum concentration of CYP3A4 substrates. Monitor therapy.
Digoxin	May increase the serum concentration of colchicine. Monitor therapy.
Fibric acid derivatives	May enhance the myopathic (rhabdomyolysis) effect of colchicine. Monitor therapy.
Fosamprenavir	May increase the serum concentration of colchicine. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are receiving ritonavir-boosted fosamprenavir. In those with normal renal and hepatic function, reduce colchicine dose as directed. Consider therapy modification.
Fusidic acid (systemic)	May increase the serum concentration of CYP3A4 substrates. Avoid combination.
HMG-CoA reductase inhibitors	Colchicine may enhance the myopathic (rhabdomyolysis) effect of HMG-CoA reductase inhibitors. Colchicine may increase the serum concentration of

	HMG-CoA reductase inhibitors. Consider therapy modification.
Idelalisib	May increase the serum concentration of CYP3A4 substrates. Avoid combination.
Luliconazole	May increase the serum concentration of CYP3A4 substrates. Monitor therapy.
Mifepristone	May increase the serum concentration of CYP3A4 substrates. Management: Minimize doses of CYP3A4 substrates, and monitor for increased concentrations/toxicity during and 2 weeks following treatment with mifepristone. Avoid cyclosporine, dihydroergotamine, ergotamine, fentanyl, pinacide, quinidine, sirolimus, and tacrolimus. Consider therapy modification.
Multivitamins/fluoride (with ADE)	Colchicine may decrease the serum concentration of multivitamins/fluoride (with ADE). Specifically, colchicine may decrease absorption of cyanocobalamin (vitamin B12). Monitor therapy.
Multivitamins/minerals (with ADEK, folate, iron)	Colchicine may decrease the serum concentration of multivitamins/minerals (with ADEK, folate, iron). Specifically, colchicine may decrease the serum concentration of cyanocobalamin. Monitor therapy.
Multivitamins/minerals (with AE, no iron)	Colchicine may decrease the serum concentration of multivitamins/minerals (with AE, no iron). Specifically, colchicine may decrease absorption of cyanocobalamin (vitamin B12). Monitor therapy.
P-glycoprotein/ABCBI inducers	May decrease the serum concentration of P-glycoprotein/ABCBI substrates. P-glycoprotein inducers may also further limit the distribution of P-glycoprotein substrates to specific cells/issues/organs where P-glycoprotein is present in large amounts (e.g., brain, T-lymphocytes, testes). Monitor therapy.
P-glycoprotein/ABCBI inhibitors	May increase the serum concentration of colchicine. Colchicine distribution into certain issues (e.g., brain) may also be increased. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are also receiving a P-glycoprotein inhibitor. In those with normal renal and hepatic function, reduce colchicine dose as directed. Consider therapy modification.
Stiripentol	May increase the serum concentration of CYP3A4 substrates. Management: Use of stiripentol with CYP3A4 substrates that are considered to have a narrow therapeutic index should be avoided because of the increased risk for adverse effects and toxicity. Any CYP3A4 substrate used with stiripentol requires closer monitoring. Consider therapy modification.
Telaprevir	May increase the serum concentration of colchicine. Management: Colchicine should not be used with telaprevir in patients with impaired renal or hepatic function. In those with normal renal and hepatic function, reduced colchicine doses (as directed) are required if used with telaprevir. Consider therapy modification.
Tipranavir	May increase the serum concentration of colchicine. Management: Colchicine should not be used with tipranavir in patients with impaired renal or hepatic function. In those with normal renal and hepatic function, reduced colchicine doses (as directed) are required if used with tipranavir. Consider therapy modification.

An NSAID would be an appropriate first-line therapy for the acute treatment of gout in E.J. because his renal function is normal. Assuming his blood pressure is adequately controlled, a short course of ibuprofen 800 mg now and every 8 hours until resolution of symptoms (usually 7–10 days) is appropriate. The ibuprofen should be prescribed on a scheduled basis rather than "as needed" to reduce inflammation and prevent breakthrough pain. The dose of 2,400 mg/day does not exceed the maximum recommended dose of 3,200 mg/day.

NONPHARMACOLOGIC INTERVENTIONS

CASE 45-2, QUESTION 6: What adjunctive therapies would be beneficial for E.J.?

The use of ice, reduction of alcohol consumption, and minor diet modification may be effective and can be considered for E.J.

Ice

The benefit of ice application to the affected joint in acute gouty arthritis should not be overlooked. Evidence from a systematic review indicates the application of ice to an affected joint for 30 minutes four times daily for 1 week reduced the pain of a gout attack when used in conjunction with oral steroids or colchicine.[53]

Alcohol Consumption

Excessive alcohol intake is known to be a risk factor for acute gout episodes. Beer was believed to be more problematic for gout than other alcoholic beverages because of its high purine content. The Health Professionals Follow-Up study[23] examined a cohort of patients with new diagnoses of gout over a 12-year time frame and found that when beer, spirits, and wine intake were examined, the greatest risk was with beer with a significant, but lesser, risk with spirits. Interestingly, wine, even more than two drinks/day, was not associated with an increased risk of gout. A smaller, independent study found that the quantity of alcohol consumed in the 24 hours before an acute attack is more important than the type of beverage consumed.[54] The current ACR,[17] EULAR,[33] and BSR/BHPR[34] guidelines recommend avoiding overuse by advocating moderation in alcohol consumption. The ACR recommends no more than two servings per day for males and one serving per day for women. Despite lack of evidence, the ACR also recommends avoiding alcohol use during an acute attack and frequent, poorly controlled gout attacks.[32] E.J. should avoid alcohol or at least limit his alcohol intake to no more than 2 servings per day.

Diet Modification

Diet has a twofold effect on the epidemiology of gout. First, obese patients are at a greater risk of developing elevated SUA levels, and gout might, in part, be related to insulin resistance of obesity.[7] In a prospective, longitudinal study of male health professionals, weight gain was strongly associated with an increased risk of gout, and weight loss was associated with a decreased risk.[55]

Second, much of the uric acid produced daily comes from metabolism of food. The excessive dietary intake of purine-rich foods, without a concomitant increase in urinary excretion, can lead to elevated SUA concentrations.[7,8] However, the type of protein and purine-rich foods that are detrimental and the true impact of these foods on the incidence of increased SUA and gout episodes are controversial issues due to the quality of evidence available.[56,57] Despite the lack of strong evidence, it is reasonable for clinicians to recommend patients limit certain foods (e.g., organ meats, beef, lamb, pork shellfish, products containing high-fructose corn syrup). Interestingly, low-fat or nonfat dairy products and coffee consumption have been associated with a decreased incidence of gout.[7,58] E.J. should be encouraged to limit or avoid purine-rich meats and fructose-containing beverages/foods and encouraged to increase consumption of low-fat dairy products.

CASE 45-3

QUESTION 1: V.D. is a 72-year-old woman who was brought to the emergency department complaining of shortness of breath and dizziness. On arrival, she is noted to have new-onset atrial fibrillation with a heart rate of 130 beats/minute and 2+ peripheral edema bilaterally to her knees. The latter is likely secondary to exacerbation of congestive heart failure caused by her rapid ventricular rate. In addition to administering diltiazem to control her heart rate, V.D. is given 40 mg of IV furosemide every 12 hours for three doses. The following day she complains of severe pain in her left great toe, and it is noted on examination to be erythematous and swollen. V.D.'s CrCl is 70 mL/minute, her SUA concentration is 7.5 mg/dL, and her blood pressure is 160/96 mm Hg. What therapeutic option would be appropriate for V.D.?

The combination of V.D.'s advanced age, acute exacerbation of heart failure, and renal dysfunction is patient-specific parameters that are relative contraindications or precautions for the use of NSAIDs for the treatment of acute gout. Therefore, alternative treatments should be considered. Colchicine is the next drug to consider, but because she is now receiving diltiazem (a moderate CYP3A4 inhibitor) the dose of colchicine would need to be reduced. Because V.D.'s pain is monoarticular, intra-articular or oral corticosteroids could be administered, but the latter would need to be tapered over the course of 10 to 21 days to avoid rebound gout symptoms. It is decided to give V.D. 1.2 mg of colchicine for one dose only, which is appropriate to avoid the diltiazem drug interaction.[47]

HYPERURICEMIA

Chronic Gout

CASE 45-3, QUESTION 2: V.D. is ready to be discharged 3 days later. Her toe is no longer inflamed, and her pain is gone. Should ULT be prescribed at discharge to prevent another gout attack?

ULT should be initiated only when patients with gout have recurrent acute attacks (at least two attacks per year), urate tophi, uric acid stones, or chronic kidney disease (Stage 2 and up) with prior gout attack and current hyperuricemia.[17,34] If these indications are absent, ULT should not be prescribed. Long-term ULT should not be started for V.D. at this time because criteria for therapy (see ACR, EULAR, and BSR/BHPR guidelines in Table 45-3)[17,33,34] are not met, and initiation of ULT during an acute episode can mobilize urate from tissues, compounding the problem.

DRUG-INDUCED HYPERURICEMIA

A patient's complete medication list should be reviewed to rule out drug-induced hyperuricemia before adding a medication to decrease SUA concentration. Perhaps, the only treatment needed would be to discontinue the offending agent. Common medications known to increase SUA include thiazide and loop diuretics, niacin, calcineurin inhibitors (e.g., cyclosporine and tacrolimus), and aspirin.[17] The authors of the ACR guidelines recommend continuing low-dose aspirin (used for cardioprotection) in patients with hyperuricemia unless with benefits of discontinuation (i.e., reduction in risk of a gout attack) outweigh the risks.[17]

The association between hyperuricemia and diuretics is well known and is dose related[59]; however, the clinical importance of

---

diuretic-induced gout attacks is now somewhat controversial. Clinicians often discontinue the diuretic, irrespective of possible ancillary benefits of diuretics (especially in HTN and CHF). A 2012 systematic review showed a trend toward increased risk for acute gout with thiazide and loop diuretics; however, the extent of the risk and its clinical significance is still unknown. Therefore, the authors state there is not enough evidence to support discontinuation of these agents in populations that have shown benefit for other comorbidities.[60] In certain cases where diuretics are thought to be a contributing factor to the precipitation of a gout attack, discontinuation of diuretic therapy may be reasonable, particularly if alternatives are available and appropriate for a patient.

GOAL OF URATE-LOWERING THERAPY

CASE 45-3, QUESTION 3: V.D. experienced another episode of acute gout 2 months later, which was treated successfully with colchicine. She is now on chronic warfarin to prevent stroke secondary to her atrial fibrillation and remains on diltiazem for heart rate control. Her blood pressure is 130/70 mm Hg, renal function is stable with a CrCl of 70 mL/minutes, and SUA is 7.2 mg/dL. Would it be appropriate to initiate ULT at this time? If so, when would you initiate treatment?

The general goals for lowering SUA concentrations are the elimination of acute gout attacks and the mobilization of urate crystals from soft tissue. The SUA concentration in a patient who has clinical gout should be decreased to 6 mg/dL or less,[17,34] which is below the saturation point for MSU. However, because some patients may experience continued gouty arthritis attacks even when the SUA is < 6 mg/dL, the ACR and BSR/BHPR guidelines recommend a goal of less than 5 mg/dL in these individuals.[17,34] The BSR/BHPR guidelines recommend as standard of care waiting 1 to 2 weeks after an acute attack to begin ULT due to risk of a recurrent attack.[34] A small, short trial studied the effect of starting allopurinol during an acute flare and was found not to worsen pain or risk of a recurrent flare. V.D. fits the criteria for initiating ULT (2 attacks in less than 1 year); however, this should be preceded by a consideration of whether drug-induced hyperuricemia could be a contributing factor. V.D.'s initial episode of gout after aggressive diuresis with IV furosemide was likely the cause of her first gout attack, but she is not currently on any drugs that cause hyperuricemia.

DRUG THERAPY OF HYPERURICEMIA

Xanthine Oxidase Inhibitors

Allopurinol

Clinical practice guidelines recommend allopurinol as a first-line agent for gout prevention.[17,33,34] It inhibits the production of uric acid and thereby decreases SUA concentrations. A 2014 systematic review of 2 clinical trials, with methodological limitations, shows that when compared to placebo allopurinol was superior at achieving target SUA concentrations, but failed to significantly reduce the frequency of acute gout attacks.[61] The ability of allopurinol to lower SUA concentrations is dose related. An allopurinol dose of 300 mg/day is typical maintenance dose, despite evidence to support that more than 50% of patients are unable to achieve target SUA at this dose or lower.[62, 63] Larger doses up to 800 to 900 mg/day may be needed for those with more severe disease.[34]

The recommended initial dose of allopurinol is 50 to 100 mg once daily and then increased in 50- to 100-mg/day increments every 2 to 5 weeks until the SUA concentration is at the desired goal of less than 6 mg/dL or until patient intolerance.[17,33,34] Starting at a low dose and titrating slowly hypothetically can reduce the risk for hypersensitivity reactions and improve tolerance in renal impairment.

Allopurinol has been associated with a life-threatening hypersensitivity syndrome that may include a desquamative, erythematous rash, fever, elevated liver function tests, and renal failure. Although hypersensitivity reactions are rare (1:1,000 in US), they are very serious.[17] If allopurinol hypersensitivity occurs, the drug should be stopped immediately because this can lead to skin necrosis, exfoliative dermatitis, Stevens–Johnson syndrome, toxic epidermal necrolysis, and even death.[64] Patients who recover should avoid future use of allopurinol, although some have been able to be desensitized and tolerate low doses.[65]

These adverse effects are more common in patients with concomitant diuretic use and preexisting renal insufficiency; therefore, dose adjustment in patients with renal impairment is recommended.[66] In the past, a nomogram based on CrCl has been used to reduce the risk of these adverse effects in renal impairment, but a subsequent study[67] challenged its efficacy and the ACR guidelines[17] recommend against this method. ACR guidelines state that doses of greater than 300 mg may be used in patients with renal impairment (Stage 4 or greater) with slow titration, close monitoring, and patient education.[17] A table detailing significant allopurinol drug interactions can be found online in Table 45-5.

Febuxostat

Febuxostat, a nonpurine XO inhibitor, was approved by the FDA in February 2009 for chronic management of hyperuricemia in patients with gout.[68] Febuxostat is more selective than allopurinol for XO and does not inhibit other enzymes involved in purine and pyrimidine metabolism. A 2012 Cochrane systematic review, with methodological limitations, evaluated six trials comparing febuxostat to allopurinol for clinical SUA-lowering effect, and found febuxostat more effective than allopurinol 300 mg in achieving SUA of less than 6 mg/dL. An important consideration in evaluating the evidence is that although the studies allowed upward titration of febuxostat to achieve maximal SUA lowering, the allopurinol dosage was not titrated to greater than 300 mg daily.[69] Because the urate-lowering effect with allopurinol is known to be dose-related, and some patients have required up to 900 mg/day to achieve a SUA less than 6 mg/dL, these results may not have allowed for an adequate comparison of efficacy between the two drugs. The same review revealed that compared to standard doses of allopurinol higher doses of febuxostat, 120 mg and 240 mg daily, increased the risk of gout flares; however, long-term follow-up studies did not detect an increased risk of flares. The FDA-approved dose in the United States is 80 mg daily; however, doses of up to 240 mg daily are approved in other countries.

In addition, adverse effects were shown to be minor and similar between both drugs in comparative studies with increases in liver function tests, nausea, diarrhea, arthralgias, and rash being the most common adverse effects with greater than 1% incidence.[62,68,70,71] Because febuxostat is more widely used, the clinician should note that thromboembolic cardiovascular events have been reported to the FDA adverse event reporting system. There are two ongoing clinical trials evaluating cardiovascular risk in both allopurinol and febuxostat.[72,73]

The starting dose of febuxostat is 40 mg once daily with a recommended dose increase to 80 mg once daily if SUA concentration is not less than 6 mg/dL by 2 weeks of therapy. It does not require dose adjustments for CrCl greater than 30 mL/minute, and the labeling provides no recommendations for use in patients with more severe renal impairment.[68] A table detailing significant febuxostat drug interactions can be found online in Table 45-6.

CHOICE OF AGENT

CASE 45-3, QUESTION 4: Because a XO inhibitor is first-line therapy to lower SUA concentration, which product should be chosen for V.D.?

Table 45-5

Allopurinol Drug Interactions

Precipitant Drug	Object Drug[a]		Description
Allopurinol	Ampicillin, amoxicillin	↑	The rate of skin appears much higher with allopurinol coadministration than with either drug alone.
Allopurinol	Anticoagulants, oral	↑	Data are conflicting. The anticoagulant action of some agents may be enhanced, but probably not that of warfarin.
Allopurinol	Cyclophosphamide	↑	Myelosuppressive effects of cyclophosphamide may be enhanced increasing the risk of bleeding or infection.
Allopurinol	Theophyllines	↑	Theophylline clearance may be decreased with large allopurinol doses (600 mg/day) leading to increased plasma theophylline levels and possible toxicity.
Allopurinol	Thiopurines	↑	Clinically significant increases in pharmacologic and effects of oral thiopurines have occurred.
ACE inhibitors	Allopurinol	↑	There is possibly a higher risk of hypersensitivity reaction when these agents are coadministered than when each drug is administered alone.
Aluminum salts	Allopurinol	↓	Pharmacologic effects of allopurinol may be decreased.
Thiazide diuretics	Allopurinol	↑	Coadministration may increase the incidence of hypersensitivity reactions to allopurinol.
Uricosuric agents	Allopurinol	↓	Uricosuric agents that increase the excretion of urate are also likely to increase the excretion of oxipurinol and thus lower the degree of inhibition of xanthine of xanthine oxidase.

[a] ↑ = object drug increased; ↓ = object drug decreased.

Although febuxostat is clearly efficacious in lowering SUA concentrations, allopurinol is also effective when the dose is appropriately titrated to response and goal SUA concentration. The ACR guidelines[17] do not recommend one over another for first-line treatment. The clinician should keep in mind the significantly higher out-of-pocket cost for febuxostat and consider patient affordability when choosing drug therapy. A 2015 cost-effectiveness analysis (from a US payer perspective) found febuxostat to be a cost-effective option compared to allopurinol at achieving a SUA level < 6 mg/dL despite the fact that the total cost of allopurinol treatment over 5 years was less ($1,882 difference between medications).[74] The National Institute for Health and Clinical Excellence (NICE), an organization that provides medical guidance to healthcare practitioners of the public health system in the United Kingdom, issued a document in 2008 that recommends febuxostat be used only in patients who are intolerant of or have contraindications to allopurinol therapy or for those who cannot achieve adequate SUA concentration lowering on allopurinol therapy.[75] V.D. does not have any contraindications to allopurinol therapy. She is on chronic warfarin, which may interact with allopurinol.[76] This warrants monitoring her international normalized ratio 5 to 7 days after allopurinol therapy is initiated and with any allopurinol dosage adjustments.

Uricosuric Agents

Probenecid is the only uricosuric agent available in the United States. Clinical practice guidelines recommend it as an second-line therapy to XO inhibitors for patients who are unable to take at least one XO inhibitor due to tolerability, contraindications, or significant drug interactions.[17] The clinical evidence for the class of uricosurics is limited to comparisons of benzbromarone, which is not available in the Unites states, to allopurinol. A 2014 Cochrane review concluded that there were no differences between these agents in the number of acute gout attacks prevented or the number of patients who discontinued therapy due to side effects.[77] However, due to the lack of head-to-head comparisons, clinicians must be cautious in extrapolating these results to probenecid. Uricosurics should not be administered to patients with impaired renal function or urolithiasis. It is well absorbed orally, and plasma concentrations peak within 2 to 4 hours. Its biologic half-life is 6 to 12 hours, and its active metabolites extend the duration of action. The usual initial dose of probenecid (250 mg twice daily for the first week of therapy) can be increased to 500 mg twice a day. If necessary, the dose can be increased further to 2 to 3 g/day. Uricosuric therapy should begin with small doses because the excretion of large amounts of uric acid increases the risk of urate stone formation in the kidney. High fluid intake to maintain urine flow of at least 2 L/day also minimizes renal stone formation. This gradual approach to the initiation of ULT also decreases the likelihood of precipitating an acute attack of gout. Common adverse effects include headache and GI upset.

Probenecid inhibits secretion of penicillins into the renal tubule, and thereby prolongs the serum half-life of penicillin and increases penicillin serum concentrations. Probenecid can also compete with salicylates for renal tubular transport, but its interactions with salicylates involve several mechanisms.[78] Low-dose aspirin for cardioprotection is unlikely to interfere with probenecid therapy. Interestingly, high-dose aspirin (e.g., greater than 1 g) has uricosuric activity of its own.[79]

Recombinant Urate Oxidase Drugs (Uricase)

Uricase, an enzyme endogenous in many animal species other than humans, converts uric acid to allantoin, which is much more soluble than uric acid and, therefore, more readily excreted into urine. Recently, two recombinant urate oxidase drugs have been developed for the treatment of hyperuricemia and gout. However, the high-incidence serious adverse reactions (23%–24%) as well as cost prohibit routine use. Rather, they should be considered as alternatives when all other ULTs have failed.[80]

Table 45-6

Febuxostat Drug Interactions

Precipitant Drug	Object Drug[a]		Description
Antacids (e.g., aluminum, magnesium)	Febuxostat	↓	Concomitant ingestion of an antacid containing magnesium hydroxide and aluminum hydroxide with an 80-mg single dose of febuxostat has been shown to delay absorption of febuxostat (approximately 1 hour) and to cause a 31% decrease in C_{max} and 15% decrease in AUC. Because AUC rather than C_{max} was related to drug effect, change observed in AUC was not considered clinically significant. Therefore, febuxostat may be taken without regard to antacid use.
Febuxostat	Didanosine	↑	Systemic exposures of didanosine are increased during coadministration. Concurrent use is contraindicated.
Febuxostat	Xanthine oxidase substrate drugs (e.g., azathioprine, mercaptopurine, theophylline)	↑	Febuxostat is a xanthine oxidase inhibitor. Inhibition of xanthine oxidase by febuxostat may cause increased plasma concentration of these drugs, leading to toxicity. Concurrent use with azathioprine or mercaptopurine is contraindicated. Use with caution when administering with theophylline.

[a] ↑ = object drug increased; ↓ = object drug decreased.

Rasburicase

Rasburicase was initially approved by the FDA for the management of hyperuricemia in children who are receiving cytotoxic chemotherapy likely to result in tumor lysis syndrome, and later received approval for the same indication in adults. Rasburicase is administered as a short IV infusion of 0.2 mg/kg daily for up to 5 days.[81] A comparative short-term study in patients with renal impairment found rasburicase was significantly more effective than allopurinol in lowering SUA concentrations at the end of 7 days of therapy.[82] Although lower-quality studies show significant reductions in SUA, rasburicase is not indicated for the treatment of hyperuricemia in patients with gout, due to its short half-life and immunogenicity. Until further studies confirm safety and longer-term efficacy in nonchemotherapy-related hyperuricemia, rasburicase should be reserved for patients with hyperuricemia who are at risk for tumor lysis syndrome.

Pegloticase

Pegloticase, the other available recombinant uricase drug available, has been shown to be effective in reducing SUA concentrations in patients who were refractory to conventional treatment in a few small randomized controlled trials.[83] It received FDA approval in 2010 for treatment in this limited population. Pegloticase is administered IV for 2 hours as a dose of 8 mg every 2 weeks.[84] It has a significant risk of anaphylaxis[85] and infusion site reactions, so each dose must be preceded by prophylaxis with an antihistamine and corticosteroid. It is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, and the usual gout flare prophylaxis is recommended for the first 6 months after initiation. Finally, antipegloticase antibodies occurred in the majority of patients studied, and this can ameliorate the SUA-lowering effects by decreasing the half-life of pegloticase. The full implication of this is unknown.

Other Agents

Some medications (e.g., ascorbic acid, antihypertensive agents, and fenofibrate) used to treat conditions commonly seen in conjunction with gout have been proven to have uricosuric properties. However, the currently available trials evaluating these agents have significant limitations and uric acid lowering is minimal. It is also important to note that to date no trials evaluating their effectiveness on clinically relevant outcomes (e.g., gout attacks) have been published. If future randomized trials show promise, some patients with hyperuricemia might be managed better by selecting drugs to manage comorbid conditions rather than requiring the use of the more traditional ULT.

Ascorbic Acid

Vitamin C has a urate-lowering effect that is believed to be mediated by competition with urate for renal tubular reabsorption.[86] However, clinical practice guidelines do not address its place in therapy, and there is a lack of high-quality evidence to support routine use for the prevention of gout attacks.[87,88]

Antihypertensive Agents

In a case–control study, calcium channel blockers and losartan have been shown to decrease the risk of incidence gout.[89] Other antihypertensive agents (e.g., β-blockers, diuretics, angiotensin-converting enzyme inhibitors, and nonlosartan angiotensin II receptor blockers) were also studied and were found to have increased risk of gout. When used with diuretics, losartan appears to mitigate the hyperuricemic effect of the diuretic.[86] It does not seem to be a class effect for the class of angiotensin II receptor blockers because, in a study, patients on losartan achieved significantly lower SUA concentrations than an irbesartan-treated group.[90] In patients with hyperuricemia and HTN, losartan and calcium channel blockers may be a viable option depending on individual patient variables.

Fenofibrate

Fenofibrate has been shown to decrease SUA concentrations by increasing renal urate excretion.[86] In addition to therapeutic lifestyle changes, fibrates (i.e., gemfibrozil, fenofibrate) or niacin is commonly used for the treatment of hypertriglyceridemia. However, with a history of gout and hyperuricemia, a fibrate would be preferred over niacin because niacin can induce hyperuricemia. Fenofibrate is a reasonable option for patients requiring a decrease in triglycerides and a history of gout; however, the selection of a medication to manage this comorbid condition also involves other clinical variables that might be equally applicable.[33,91,92]

FLARE PROPHYLAXIS DURING INITIATION OF ULT

CASE 45-3, QUESTION 5: V.D. is started on allopurinol 100 mg orally once daily for initial ULT. Her SUA concentration will be checked, and her allopurinol will be increased by 50 to 100 mg/day in 2 to 4 weeks if needed until she reaches the goal of less than or equal to 6 mg/dL. What other drug therapy should also be considered when starting ULT?

Paradoxically, initiation of ULT can precipitate acute gout attacks. Guidelines recommend prophylaxis with anti-inflammatory agents for all patients when ULT is initiated.[32–34] The following anti-inflammatory agents should be considered, in order of preference: colchicine, low-dose NSAIDs, and oral corticosteroids.[32] However, when choosing prophylactic therapy, one should also consider patient comorbidities, potential drug–drug interactions, and tolerance issues. Upon initiation of ULT, anti-inflammatory therapy should be continued for at least 6 months. A shorter duration of 3 months may be reasonable in patients without evidence of tophi who achieve SUA target concentrations. V.D. would be a candidate for flare prophylaxis. As stated above, V.D.'s advanced age, acute exacerbation of heart failure, and renal dysfunction are patient-specific parameters that are relative contraindications or precautions for the use of long-term NSAID therapy for flare prophylaxis. Colchicine would be a reasonable option because it is considered first line and she tolerated colchicine during acute attacks. The colchicine dose for flare prophylaxis is 0.6 mg once or twice daily for 6 weeks. V.D. should be monitored for adverse drug reactions.

MONITORING AND FOLLOW-UP

In addition to monitoring for subjective and objective evidence of drug-related adverse effects, SUA concentrations should be monitored monthly until at goal, then every 6 to 12 months, thereafter. The optimal duration of ULT is unclear. Patients with mild gout may go years without experiencing repeat attacks after discontinuation of ULT. Lower SUA concentrations during treatment correlate with a longer interval between acute attacks or before tophi reappear. The majority of patients on long-term ULT are likely to experience recurrent acute attacks, tophi, or both if treatment is stopped.[93] The decision when to discontinue ULT should be made based primarily on patient preference after a shared-informed discussion.

Asymptomatic Hyperuricemia

CASE 45-4

QUESTION 1: T.M., a 50-year-old man, is seen by his physician for a routine evaluation. His physical examination is unremarkable, and his laboratory evaluations are all within normal limits except for a SUA concentration of 9.5 mg/dL. Should his hyperuricemia be treated?

Individuals with high SUA concentrations are more likely to develop acute gouty arthritis than normouricemic individuals. A large percentage of hyperuricemic patients may never experience an acute attack of gout.[2] Therefore, it would be excessive to treat all hyperuricemic individuals with uric acid-lowering medications for lifetime solely to prevent acute attacks of gouty arthritis. If an attack should occur, it can be treated quickly and easily, and if the patient has at least two attacks in a year, ULT can be considered. The ACR guidelines chose not to address this condition due to lack of quality evidence.[17]

The key issue in the treatment of hyperuricemia concerns the effect of uric acid on renal function. Renal disease was commonly associated with gout, and renal failure was believed to be the eventual cause of death in as many as 25% of gouty patients. However, the coexistence of gout and renal insufficiency without HTN is rare.[94] Therefore, the consensus now seems to be that hyperuricemia by itself has no deleterious effect on renal function.[95,96]

PHARMACIST'S ROLE

The pharmacist has an important role in the education and management of gout. As noted several times in this chapter, there are significant drug–drug interactions associated with a majority of the medications used to treat both acute and chronic gout. A 2008 retrospective cohort study showed that 28% of patients did not meet with a provider prior to initiation of ULT and 56% of patients were nonadherent with

ULT.[97] Patient education about the role of the medication, including the importance of adherence and how to monitor for and manage adverse drug reactions in the treatment of gout, is an essential part of therapy. In the cases where a provider visit did not occur prior to starting ULT, a pharmacist could have been a resource for education. Pharmacists are equipped with the knowledge and skills to monitor for drug–drug interactions, monitor and educate about medication adherence, and provide general education about gout and lifestyle recommendations. Also, open communication with the patient's primary-care provider has the potential to improve the patient experience related to this condition.

Connective Tissue Disorders

Julie L. Olenak and Jonathan D. Ference

CORE PRINCIPLES

		CHAPTER CASES
1	Ninety percent of patients who are affected by systemic sclerosis also have signs and symptoms consistent with Raynaud phenomenon.	**Case 46-1 (Questions 1, 2), Table 46-1**
2	Nifedipine, prazosin, and losartan may decrease severity and frequency of symptoms of Raynaud syndrome.	**Case 46-1 (Question 3), Table 46-3**
3	Many authorities believe polymyalgia rheumatica and temporal arteritis are manifestations of the same underlying process occurring at different times during the clinical course. However, they each have characteristic symptoms and are treated differently.	**Case 46-2 (Questions 1–3), Table 46-4**
4	Reactive arthritis is secondary to certain genitourinary, gastrointestinal, or respiratory infections. Patients with the HLA-B27 gene are more susceptible to spondyloarthritis.	**Case 46-3 (Question 1), Table 46-5**
5	Patients with documented active infections, and their partners when caused by a sexually transmitted disease, should be offered antibiotics. However, efficacy of prolonged antibiotics as a treatment of reactive arthritis is conflicting.	**Case 46-3 (Question 2)**
6	Nonsteroidal anti-inflammatories are appropriate initial therapy for reactive arthritis to control pain and inflammation.	**Case 46-3 (Question 2)**
7	In severe or prolonged cases of reactive arthritis, steroids, DMARDs, and biologicals may be considered.	**Case 46-3 (Question 3)**
8	Polymyositis and dermatomyositis should initially be treated with high-dose corticosteroids. Immunosuppressive agents are recommended if the disease is not controlled with corticosteroids alone, if the response is positive but steroid sparing effects are desired, or if the condition presents initially with extramuscular complications.	**Case 46-4 (Questions 1, 2)**

INTRODUCTION

Despite new knowledge in the immunology and the pathogenesis of the different connective tissue diseases (CTDs), the etiology of these conditions remains unclear.[1] Diagnosing CTDs can be difficult because of the complexity of the diseases and the varying presentation of symptoms. The patient's reported history of symptoms, results of the physical examination, and laboratory testing help guide the diagnosis of a CTD.[1] It has been reported that as many as half of patients who have a diagnosed CTD had been identified as having undifferentiated connective tissue disease.[2] It can take years for a patient to be diagnosed and meet classification criteria. Diffuse CTDs include systemic lupus erythematosus (SLE), scleroderma, polymyositis, dermatomyositis, rheumatoid arthritis, and Sjögren syndrome. Patients may present with findings consistent with more than one CTD, and symptoms generally do not all appear simultaneously. Mixed CTD is an overlap of autoimmune disease features that can include myositis, scleroderma, and lupus.[1,2]

GENERAL SIGNS AND SYMPTOMS

Many patients such as those with SLE can have arthralgias and arthritis as part of the inflammatory disease associated with their CTD. Inflammatory disease is suggested by morning stiffness of greater than 1 hour (a similar problem occurs with sitting or resting), swelling, fever, weakness, and systemic fatigue. In some patients, activities of daily living and function may be excellent despite pain and deformity; in others, because of psychologic and systemic disease, there may be poor function with minimal articular involvement. Other psychosocial aspects of their life, including sexuality, may be affected by many of the inflammatory disorders.

Dermatologic changes are often associated with a particular rheumatic disease. Examples include alopecia with SLE, onycholysis and keratoderma blennorrhagica with reactive arthritis, buccal or genital ulcers with SLE or Reiter syndrome, Raynaud phenomenon with SLE or systemic sclerosis, calcinosis and rash over the knuckles (Gottron papule) with dermatomyositis, and sun sensitivity malar rash with SLE. The presence of nodules, tophi, telangiectasia, or vasculitic changes also may be detected, helping the clinician differentiate which inflammatory disease is present and what management is necessary.

The CTDs are commonly associated with musculoskeletal changes. Joints may display warmth, redness and effusion, synovial thickening, deformities, decreased range of motion, pain on motion, tenderness on palpation, and decreased function. Often, a patient's hand and arm function, as well as gait, may be altered. In addition to the signs and symptoms used to differentiate various rheumatic diseases, laboratory evaluation of patients with rheumatic complaints can often define the extent of disease or detect other organ systems that may be involved.

SELECTED CONNECTIVE TISSUE DISEASES

CTDs and rheumatic diseases encompass a wide range of disorders that are inflammatory in nature and related to the immune system. The following are some of the conditions that are encountered in clinical practice and will be discussed in this chapter: scleroderma, polymyalgia rheumatica, temporal arteritis, reactive arthritis, polymyositis, and dermatomyositis. The reader is also referred to Chapter 33, which covers SLE.

Systemic Sclerosis (Scleroderma)

Systemic sclerosis, or systemic scleroderma, is a CTD associated with autoimmunity characterized by excessive extracellular matrix deposition and vascular injury to the skin and other visceral organs.[3] Systemic sclerosis can be classified into distinct clinical subsets based on the patterns of skin and internal organ involvement, autoantibody production, and patient survival.[3] The most common subsets include limited cutaneous (approximately 60% of patients) and diffuse cutaneous (approximately 35% of patients).[3] The term overlap syndrome may be applied to patients when features common in one or more of the other CTDs are present and affect approximately 11% of patients diagnosed with systemic sclerosis. The limited cutaneous subset is diagnosed when skin thickening is limited to the areas distal to the elbows and knees. A constellation of dysfunctions known as CREST (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia) syndrome is a variant of limited cutaneous systemic sclerosis.[3]

More women than men suffer from systemic sclerosis (female- to-male ratio, 4.6:1), although the mean age at diagnosis does not differ between men and women.[4] Onset of systemic sclerosis generally begins in adults between 30 and 50 years of age and is rare in children and seniors older than 80 years of age.[5] The prevalence is estimated at 276 cases/million adults in the United States.[5] African-American patients are twice as likely as non–African-American patients to have diffuse disease, with the annual incidence in African-American women being twice that of Caucasian women.[4,6] Likely and possible risk factors for the disease include environmental exposure to silica dust (e.g., coal miners) and the presence of a connective tissue growth factor polymorphism, respectively.[7] At this time, there is no conclusive evidence to support an association between silicone breast implants and systemic sclerosis, or any other CTD.[7] Cigarette smoking is not associated with an increased risk of systemic sclerosis.[8]

The underlying pathophysiologic changes that lead to systemic scleroderma remain unknown, but many believe that it results from a lymphocyte-mediated autoimmune reaction with endothelial cells, activated immune cells, and fibroblasts playing a key role in the process. It is hypothesized that the process is initiated by an immune attack on the endothelium leading to endothelial cell activation or injury. This is followed by activation of the fibroblasts, resulting in subendothelial connective tissue proliferation, narrowing of the vascular lumen, and Raynaud phenomenon. T cells are then selectively activated and populate the affected areas such as the dermis and lung tissue. These cells produce cytokines that stimulate resident fibroblasts to produce excessive amounts of procollagen, which is then converted extracellularly to mature collagen. Later, when the inflammatory process subsides, the fibroblasts revert back to normal. The most common, and serious, complications of systemic scleroderma involve the pulmonary system and may include fibrosis or interstitial lung disease as well as pulmonary vascular disease leading to pulmonary arterial hypertension. It is estimated that pulmonary involvement occurs in 40% of individuals and contributes from 13% to 17% of deaths from systemic scleroderma.[7] Other complications include, but are not limited to, poor wound healing, arrhythmia, heart failure, renal failure, and esophageal strictures.[7]

CASE 46-1

QUESTION 1: T.P., a 58-year-old African-American woman with known limited cutaneous scleroderma, presents to your outpatient clinic complaining of pain and discoloration of the fingers on both hands. She describes discoloration as an intermittent loss of color from normal to a pale appearance, and the pain as intermittent numbness and tingling accompanying the loss of color. T.P. states the symptoms only appear when she is exposed to a cold environment. These symptoms are interfering with her quality of life and activities of daily living. In terms of other symptoms, T.P. also experiences intermittent development of thickened, pitted, rough skin patches located distal to her elbows bilaterally. She has no other significant past medical history, nor takes any medications on a regular basis. The physical examination findings revealed patches of skin thickening and nonpitting induration on upper torso. Telangiectasias are also noted in this area. Laboratory samples drawn last week show her ANA is negative and the basic metabolic panel, complete blood count, and liver function tests are all normal. What subjective and objective data present in T.P.'s case are consistent with limited cutaneous scleroderma?

T.P. is complaining of classic symptoms of Raynaud syndrome, which is a common clinical feature of limited cutaneous scleroderma, present in over 95% of cases. In addition, skin fibrosis that is present distal to the elbow or knees, and telangiectasias are suggestive of limited cutaneous scleroderma as opposed to diffuse cutaneous scleroderma. Because ANAs may be present in unaffected patients and absent in afflicted patients, ANA test results must be interpreted within the clinical context and should not be relied on as a sole diagnostic marker.[9]

CASE 46-1, QUESTION 2: Based on these signs and symptoms, which variant(s) of limited cutaneous scleroderma is likely present?

Over 95% of patients who are affected by systemic sclerosis also have signs and symptoms consistent with Raynaud phenomenon, as it is seen with T.P. Patients will typically complain of recurrent, intermittent vasospastic episodes resulting in a color change in the fingers or toes after being exposed to cold temperatures. Vasoconstriction may lead to local cyanosis and accompanying pain and numbness, with flushing noted on rewarming. Other parts of the body may also be affected, such as the nose, ears, tongue, and nipples.

Table 46-1

Common Clinical Features of Systemic Sclerosis

Subset	Skin Fibrosis	Lung Involvement	Visceral Organ Involvement	Physical Examination Findings
Limited cutaneous	Areas distal to the elbows and knees[a]	Pulmonary arterial hypertension	Severe GERD and Raynaud phenomenon	Telangiectasia, calcinosis cutis, sclerodactyly, digital ischemic complications
Diffuse cutaneous	Areas proximal or distal to the elbows and knees[a]	Interstitial lung disease	Scleroderma renal crisis	Tendon friction rubs, pigment changes

[a] May affect the face.

GERD, gastroesophageal reflux disease.

Common clinical features can be used to distinguish between limited and diffuse cutaneous systemic sclerosis subsets (Table 46-1).[3] In addition, variants of the condition may exist within each subset based on the presence of other symptoms. Manifestations of systemic sclerosis differ based on the organ system(s) involved (Table 46-2).[3] Other disorders that may have similar clinical characteristics, such as amyloidosis and mixed CTD, should be considered and ruled out before the diagnosis of systemic sclerosis. The ACR/EULAR criteria for the diagnosis of systemic sclerosis require the presence of one lone major criterion (skin thickening of fingers of both hands extending proximal to metacarpophalangeal joints) or two minor criteria (skin thickening of fingers, fingertip lesions, telangiectasia, abnormal nailfold capillaries, pulmonary arterial hypertension and/or interstitial lung disease, Raynaud phenomenon, or presence of any of systemic sclerosis-related autoantibodies).[10] Skin biopsy is recommended to confirm scleroderma if the clinical picture is unclear. Separate criteria exist for the diagnosis of juvenile systemic sclerosis.[10] The overall course of systemic sclerosis is highly variable and unpredictable. However, after a remission occurs, relapse is uncommon.

Table 46-2

Manifestations of Systemic Sclerosis

Organ System	Manifestations
Cardiovascular	Abnormal cardiac conduction, congestive heart failure, pericardial effusion, digital ischemic changes, Raynaud phenomenon
Gastrointestinal	Barrett esophagitis or strictures, gastroesophageal reflux disease, dysphagia, halitosis, chronic cough, dental erosions
Genitourinary	Sexual dysfunction, dyspareunia, impotence
Musculoskeletal	Flexion contractures, muscle atrophy, puffy hands, inability to make a tight fist, weakness
Pulmonary	Interstitial lung disease, pulmonary arterial hypertension, basilar and course crackles, dyspnea on exertion
Renal	Renal crisis
Skin	Calcinosis, pruritus, thickened skin, tight skin, excoriations, scabbing, loss of pigmentation

Adapted with permission from Hinchcliff M, Varga J. Systemic sclerosis/scleroderma: a treatable multisystem disease. Am Fam Physician. 2008;78:961.

CASE 46-1, QUESTION 3: At this time, which therapeutic agent(s) is recommended to treat T.P.'s manifestations and symptoms of systemic sclerosis?

Clinical practice guidelines exist, which may assist the clinician when determining treatment for systemic sclerosis.[12] However, there is not a specific therapy for systemic sclerosis. Rather, treatment is mainly supportive and symptomatic in nature, targeting the specific organ(s) affected (Table 46-3).[13] Therefore, the primary goals of therapy are to improve the quality of life and minimize the risk of complications. Based on T.P.'s current symptoms, initiating therapy with the dihydropyridine calcium-channel blocker nifedipine is an appropriate option to achieve symptom control. Compared with placebo, nifedipine and prazosin modestly reduced the severity and frequency of Raynaud ischemic attacks.[14,15] However, when losartan was compared with low-dose nifedipine in a nonblinded, randomized, controlled trial (RCT), losartan users experienced a decrease in severity and frequency of Raynaud symptoms in a 12-week period.[16] This should not be considered as definitive evidence that losartan is superior as the lack of blinding may have resulted in an overestimation of losartan's benefit. Although tadalafil monotherapy does not appear effective for Raynaud phenomenon due to systemic sclerosis, when added to a calcium-channel blocker the combination appears to improve symptoms and reduce digital ulcers compared to calcium-channel blocker alone.[17,18] Bosentan (which is restricted in the United States and approved for the treatment of symptomatic pulmonary hypertension) has been shown to decrease the occurrence of digital ulcers caused by Raynaud phenomenon.[19] Compared to placebo, atorvastatin 40 mg daily reduced the number of new digital ulcers in patients with Raynaud phenomenon and systemic sclerosis during a four-month randomized trial: mean number of new digital ulcers per patient 1.6 versus 2.5 comparing atorvastatin versus placebo, respectively.[20] Patients who develop pulmonary artery hypertension early the treatment with an angiotensin-converting enzyme inhibitor may improve prognosis in scleroderma renal crisis.[12,21] For patients who develop pulmonary hypertension, treatment with bosentan, ambrisentan, sildenafil, epoprostenol infusion, or other prostanoids (treprostinil, iloprost) may be considered because they have all been shown to improve functional capacity.[7] The effects of cyclophosphamide, an antineoplastic agent, demonstrated in clinical trials are conflicting. In an RCT comparing cyclophosphamide with placebo in patients with scleroderma lung disease, use of this agent modestly reduced dyspnea and disability while improving lung function.[22] However, a meta-analysis of three RCTs and six cohort studies concluded that cyclophosphamide does not result in significant clinical improvement of pulmonary function.[23] Because this is a potentially toxic drug, patients who take it require close monitoring.

Table 46-3

Treatment Options for Manifestations of Systemic Sclerosis

Manifestation	Treatment Options
Raynaud phenomenon	Nifedipine, verapamil, losartan, prazosin, iloprost, calcium-channel blocker + tadalafil
Pulmonary hypertension	Bosentan, sildenafil, enalapril, iloprost
Interstitial lung disease	Cyclophosphamide, prednisone
Renal crisis	Angiotensin-converting enzyme inhibitors, dialysis, or kidney transplant
Skin fibrosis	Methotrexate, cyclosporine, D-penicillamine
Arthralgias	Acetaminophen and NSAIDs
GERD	Proton pump inhibitors, H2 antagonists, prokinetic agents
Pruritus	Antihistamines, low-dose topical steroids

GERD, gastroesophageal reflux disease; NSAID, nonsteroidal anti-inflammatory drug; H2, type 2 histamine receptor.

Polymyalgia Rheumatica and Temporal Arteritis (Giant Cell Arteritis)

Polymyalgia rheumatica (PMR) and temporal arteritis, also known as giant cell arteritis (GCA), are closely related clinical syndromes that usually affect the elderly and frequently occur together. Many authorities believe them to be different phases of the same underlying disease process. Polymyalgia rheumatica is 2 to 3 times more common than GCA. However, about 27% to 53% of persons with GCA also have PMR, and 18% to 26% of those with PMR also have GCA.[24] PMR can occur before, with, or after the development of GCA. Inflammation is the hallmark of both conditions. PMR is characterized by aching and morning stiffness in the cervical region and shoulder and pelvic girdles, and may result in disability.[25] Inflammation as a result of GCA most commonly involves the temporal artery, but arteries in other parts of the body can also be affected.[26] Despite certain similarities, PMR and GCA have distinct symptoms, corticosteroid requirements for treatment, and prognoses.

The incidence of PMR and GCA increases in patients after the age of 50 and peaks in those 70 to 80 years of age.[25] GCA is the most common vasculitis among the elderly and can lead to blindness if not diagnosed and treated in a timely manner. Likewise, without treatment, PMR can lead to significant morbidity and disability. Patients with PMR are also at an increased risk of peripheral arterial disease. The primary risk factor for both conditions is age, and both occur more frequently in women than in men. PMR is seen mainly in people of north European ancestry and generally affects whites more commonly than African-Americans, Hispanics, Asians, and Native Americans.[26] The incidence of PMR is 5.9/10,000 patients/year in the United States, with an overall prevalence in the United States of about 740/100,000: 532 for men and 925 for women.[27] The incidence of GCA is 0.17 new cases annually per 1,000 persons older than 50 years of age with a prevalence of 2/1,000 persons.[28]

Although the exact pathogeneses of PMR and GCA are yet to be determined, they are both thought to arise from an autoimmune or inflammatory dysfunction involving similar cellular immune responses from T cells, antigen-presenting cells, macrophage-derived inflammatory cytokines, genetic human leukocyte antigen molecules, and macrophages. A viral cause has been suspected but not confirmed for both PMR and GCA, and some studies demonstrate a cyclic pattern in PMR incidence pointing to environmental infectious triggers (e.g., parvovirus B19, Mycoplasma pneumoniae, and Chlamydia pneumoniae) as potential causes.[25,29] Branches of the internal and external carotid arteries are most commonly affected in those with GCA, and biopsies often reveal inflammatory changes that lead to a narrowing or occlusion of the vessel and ischemia distal to the lesion.[26] Systemic inflammation is the most prominent feature in PMR, but inflammation of the blood vessels is often clinically undetectable.[26]

CASE 46-2

QUESTION 1: D.C. is an 85-year-old white man presenting to the emergency department complaining of new-onset morning aching pain and stiffness in his shoulders and upper arms. He states his symptoms developed 3 weeks ago and have progressed to the point where his pain and limited range of motion are keeping him from performing activities of daily living. D.C. denies headaches or vision disturbances, but is complaining of overall malaise, fatigue, and anorexia. He has a past medical history significant for hyperlipidemia, type 2 diabetes mellitus, and hypertension. He has been taking his current medications for the past 2 years, which are adequately controlling his hyperlipidemia, diabetes, and hypertension. His current medications include simvastatin 40 mg daily, metformin 1,000 mg twice daily, lisinopril/hydrochlorothiazide 40/25 mg daily, and aspirin 81 mg daily. His physical examination was negative for decreased muscle strength. Limited range of shoulder and upper arm motion is noted along with tenderness of these areas on palpation. Routine baseline laboratory values are within normal limits, with an ESR of 75 mm/hour. D.C. was admitted to a general medical ward with a diagnosis of PMR and was started on prednisone. What signs and symptoms present in this case differentiate PMR from GCA?

No conclusive laboratory test for PMR or GCA exists, and nonspecific clinical features and the absence of physical signs often complicate diagnosis. Appropriate diagnosis requires a thorough history and physical examination. Distinguishing between the two disorders is of importance, as GCA can lead to blindness and requires higher doses of treatment medications. The typical onset of PMR is acute in nature. However, as is the case with D.C., most who present for a medical evaluation describe their symptoms as occurring for 1 month or longer.[26] D.C. is also exhibiting common complaints associated with PMR, which include aching pain and morning stiffness in the shoulders and upper arms, hips and thighs, or neck and torso. The shoulders are affected in 95% of cases. New-onset GCA often manifests as a new headache or a headache that is described as different from previous headaches and has been occurring for 2 to 3 months. Constitutional symptoms such as fatigue, anorexia, and weight loss in an older patient often accompany headaches seen in GCA.[24] The absence of headache in D.C. further supports the diagnosis of PMR. Common findings associated with both conditions are presented in Table 46-4.[26] The most useful laboratory test for diagnosing PMR is the ESR. Patients with GCA usually have an ESR greater than 40 to 50 mm/hour; rates of greater than 100 mm/hour are common. A normal ESR is very helpful in ruling out GCA in corticosteroid-naïve patients; however, an elevated ESR (>100 mm/hour) is only minimally helpful in ruling out GCA.[30] Three or more of the following criteria that are present are 93% sensitive and 91% specific for GCA: age of onset of disease greater than or equal to 50 years, new headache, temporal artery abnormality, ESR greater than or equal to 50 mm/hour, or abnormal findings on biopsy of the temporal artery.[31] The BSR/BHPR guidelines recommend biopsy of the temporal artery for the diagnosis of GCA.[32] An abnormal biopsy in the context of positive clinical findings described in Table 46-4 as well as an elevated ESR is strongly predictive of neuro-ophthalmic complications. However, a negative biopsy result does not preclude the diagnosis of GCA if there is strong clinical suspicion.

Table 46-4

Common Findings Associated with Polymyalgia Rheumatica and Giant Cell Arteritis (GCA)

Polymyalgia Rheumatica	Giant Cell Arteritis
Age ≥50 years	Age ≥50 years
ESR >50 mm/hour	ESR >50 mm/hour
Anemia (mild, normochromic, normocytic)	Anemia
Aching, pain, and morning stiffness in the shoulders and upper arms, hips and thighs, or neck and torso	Headache: temporal with temporal artery involvement, or occipital with occipital artery involvement
Symptoms of systemic inflammation	Visual symptoms or jaw claudication
	Fever, weight loss, depression, fatigue Arthralgias

ESR, erythrocyte sedimentation rate.

CASE 46-2, QUESTION 2: What other inflammatory conditions should be considered and excluded before making the diagnosis of PMR or GCA in D.C.?

Other inflammatory or autoimmune disorders, such as fibromyalgia, myalgias from statin therapy, osteoarthritis, polymyositis, and rheumatoid arthritis, should be considered and excluded before the diagnosis of PMR or GCA.[26] Specific alternatives that should be included in the differential diagnosis of PMR include hyperparathyroidism, Parkinson disease, thyroid disorders, adhesive capsulitis, pseudogout, cervical spondylosis, SLE, or multiple myeloma.[24] Other vasculitides (Wegener granulomatosis, polyarteritis nodosa, microscopic polyangiitis), Takayasu arteritis, malignancies, herpes zoster, and migraines (or other causes of headaches) should be included in the differential diagnosis of GCA.[33]

CASE 46-2, QUESTION 3: What is the preferred initial treatment approach for PMR in D.C.? Explain the difference(s) in this approach as compared with those for GCA.

Owing to its anti-inflammatory properties, corticosteroids are considered first-line therapy for either PMR or GCA. Early visual loss may occur in up to 20% of patients and rarely improves once present. Therefore, initiation of corticosteroid treatment should not be delayed pending temporal artery biopsy results.[24] When PMR and GCA occur simultaneously, higher corticosteroid doses (indicated for the treatment of CGA) are required to prevent significant complications. For the treatment of PMR, the British Society for Rheumatology (BSR) and the British Health Professionals in Rheumatology (BHPR) recommend standard initial treatment with oral prednisone 15 mg/day for 3 weeks, 12.5 mg/day for 3 weeks, and 10 mg/day for 4 to 6 weeks, then decrease by 1 mg every 4 to 8 weeks.[29] An alternative treatment regimen includes intramuscular methylprednisolone 120 mg every 3 to 4 weeks, decreased by 20 mg every 2 to 3 months. Beginning low-dose prednisone may improve D.C.'s PMR symptoms within days, but some optimal results could take several weeks to achieve and most patients can expect to receive therapy for 1 to 2 years. Treatment should be tailored to patient symptoms, and inflammatory markers should be followed. Attempts to taper the dose to avoid long-term adverse drug events (e.g., osteoporosis, hypothalamus–pituitary–adrenal axis suppression) should be made once acute relief has been achieved. Tapering the dose (e.g., 1 mg/day/week) should be individualized and based on symptom response because it may take years owing to symptom flares. The Polymyalgia Rheumatica Activity Scale, a disease activity assessment, may be used to monitor and adjust therapy and patient response.[26]

As opposed to PMR, treatment for uncomplicated (no jaw or tongue claudication or visual changes) GCA should begin with high-dose prednisolone (40–60 mg/day).[29] Complicated GCA (evolving visual loss or history of amaurosis fugax) should be treated with IV, methylprednisolone 500 mg to 1 g/day for 3 days, followed by oral prednisolone 60 mg/day.[29] A corticosteroid taper can be initiated after 4 weeks of treatment and resolution of symptoms and normalization of ESR/CRP. It is recommended to decrease the prednisolone dose by 10 mg every 2 weeks until 20 mg is reached, then decrease by 2.5 mg every 2 to 4 weeks until 10 mg is reached, and then decrease by 1 mg every 1 to 2 months.[29] Most will achieve a dose of 7.5 to 10 mg/day after 6 months of therapy, but relapses are common and are managed by restarting steroid therapy or increasing the dose to previous beneficial amounts.[25] The use of low-dose aspirin may reduce the incidence of cranial ischemic complications.

The use of methotrexate as adjuvant therapy for PMR and GCA is not routinely recommended, and its evidence of symptom relief benefit is conflicting.[26] However, a single RCT demonstrated that the use of methotrexate 10 mg once weekly in addition to prednisone in those with GCA resulted in an overall decrease in the amount of prednisone required and in relapse rates.[35] Relapses are common in both PMR and GCA and may be managed by restarting steroid therapy or increasing the dose to previous levels that controlled symptoms, if already receiving steroids. All patients on long-term corticosteroids should be offered calcium (1,200 mg/day) and vitamin D (800 international units/day) for prevention of osteoporosis and be monitored for other complications of steroid therapy. Patients at risk for gastritis should receive prophylactic protection with a proton pump inhibitor.

Patients being treated for PMR or GCA should be monitored closely in response to treatment and disease progression. It is recommended that the first follow-up visit should take place 1 to 3 weeks after the start of corticosteroids.[29] Subsequent visits should occur at 6 weeks as well as 3, 6, 9, and 12 months, or on an as-needed basis if relapses or adverse events occur. At each visit, patients should be assessed for specific symptom improvement and routine blood work should include ESR, CRP, CBC, and CMP. Bone mineral density testing every 2 years may be considered in patients receiving long-term corticosteroids. Professional guidelines recommend a chest X-ray every 2 years to assess for aortic aneurysm in patients diagnosed with GCA.[29] However, a systematic review of imaging studies found limited evidence to guide screening recommendations for thoracic aortic aneurysm/dilation because a chest X-ray may not be sensitive enough to detect thoracic aortic aneurysms.[34]

Reactive Arthritis

Reactive arthritis is defined as peripheral arthritis often accompanied by one or more extra-articular manifestations that appear after certain infections of the genitourinary, gastrointestinal, or respiratory infection. Table 46-5 lists bacterial pathogens associated with the development of reactive arthritis.[36–39] In addition, it shares features with other forms of spondyloarthropathies, which is the grouping it falls under. Reiter syndrome was previously used to describe this condition, but the term reactive arthritis has become the preferred term. The term classic "Reiter triad" associated with this condition was used to describe the specific combination of arthritis, urethritis, and conjunctivitis.[37] The presentation of arthritis is usually a large joint monoarthritis or oligoarthritis usually in the lower extremities, and/or enthesitis which is the inflammation of the entheses. This is the site where the tendon or ligament enters the bone.[36] Typically, the inflammatory disorder would occur 1 to 6 weeks after the infection.[37] The clinical course of reactive arthritis is variable and usually runs a self-limited course of 3 to 12 months.[36] Mortality from reactive arthritis is not common and results from cardiac complications such as aortitis. Approximately 10% to 20% of patients may continue to have chronic, destructive, and disabling arthritis or enthesitis within 2 years after the onset of symptoms. Ten to fifteen percent may progress to ankylosing spondylitis.[39]

The annual incidence reported varies between 9 and 27 for reactive arthritis/100,000/year. Patients with an acute Chlamydia infection develop reactive arthritis. Reactive arthritis most frequently occurs in patients between 20 and 40 years of age, but it can occur at any age. In general, it occurs more frequently in men than in women following genitourinary infection, which is most commonly a sexually transmitted disease. Following bowel infections, the prevalence is equal between men and women.[37]

Reactive arthritis is considered a sterile inflammatory response to a remote infection. Reactive arthritis usually occurs after an infection in a genetically susceptible person, which has been identified as a likely risk factor. Genetics may play a role in pathogenesis of spondyloarthropathies; 30% to 50% of patients are surface antigen HLA-B27 positive, which presents antigenic peptides to T cells. These patients are susceptible to a more severe and prolonged disease.[37] The HLA-B27 gene has a higher prevalence in the Caucasian population.[39]

Table 46-5

Examples of Bacterial Pathogens Associated with the Development of Reactive Arthritis

Gastrointestinal
Salmonella enteritidis and typhimurium Shigella flexneri
Yersinia enterocolitica and pseudotuberculosis
Campylobacter jejuni
Escherichia coli
Clostridium difficile
Genitourinary
Chlamydia trachomatis Neisseria gonorrhoeae
Respiratory
Chlamydia pneumoniae Group A β-hemolytic streptococcus

Philadelphia, PA: Saunders Elsevier; 2013:1221; Reactive arthritis. In DynaMed [Internet]. Ipswich (MA): EBSCO Information Services. 1995 – [cited 2010 March 23]. http://www.dynamed.com. Registration and login required. Accessed July 8, 2015; Hannu T. Reactive arthritis. Best Pract Res Clin Rheumatol. 2011;25:347; Selmi C, Gershwin ME. Diagnosis and classification of reactive arthritis. Autoimmun Rev. 2014;13:546.

Onset of symptoms typically occurs 1 to 3 weeks later and may present in an insidious or acute manner. Patients usually present with a chief complaint of mucocutaneous lesions, joint stiffness, myalgia, and low back pain that is worse with rest. Table 46-6 describes the clinical manifestations of reactive arthritis. It may present as arthritic in nature or as dysfunctions of the ocular, skin, genitourinary, or cardiac systems. Urethritis, mild dysuria, and a mucopurulent urethra are the most common symptoms that occur in men. Women may have dysuria, vaginal discharge, and purulent cervicitis or vaginitis. Arthritic complaints are usually asymmetrical, involving the lower extremities, and are associated with the appearance of a "sausage finger" digit.[36]

CASE 46-3

QUESTION 1: T.K. is a 37-year-old man who presented to the outpatient primary-care clinic 2 weeks after the onset of a low-grade fever associated with pain and stiffness in his left knee and right ankle, pain on urination, and red, irritated eyes. He reports no recent injuries. The patient reports that the last time he engaged in unprotected sex was 3 weeks ago. T.K. denies experiencing chest pain, skin rash, photosensitivity, genital lesions, or urethral discharge and hematuria. Swelling, erythema, and tenderness of the left knee joint, as well as signs of conjunctivitis, were the only findings noted on physical examination. A urine Chlamydia rapid test with first void was positive.

He reports no current medical conditions and a family history of psoriatic arthritis.

Based on the history of symptoms present in this case, what supports a diagnosis of reactive arthritis?

T.K. presents with multiple symptoms following a confirmed infection with Chlamydia trachomatis. He is presenting with an inflamed joint in the lower extremity and also conjunctivitis. Urethritis can be a symptom associated with reactive arthritis but in this case overlaps as a potential symptom of an active Chlamydia infection. A family history of psoriatic arthritis, which is also under the classification as a spondyloarthropathy, may indicate a risk factor for severe or chronicity if T.K. has the HLA-B27 gene. Laboratory testing for the gene is not required for diagnosis.[36,37]

Table 46-6

Clinical Signs of Reactive Arthritis

Musculoskeletal System
Arthritis affecting 1–4 joints Entheses
Extra-articular disease
Skin Manifestations
Keratoderma blennorrhagica on soles and/or palms Circinate balanitis on penile gland
Ocular Manifestations
Mucosal ulcers Conjunctivitis
Uveitis

Source: Hill Gaston JS. Reactive arthritis and undifferentiated spondyloarthritis. In: Firestein G et al, eds. Kelley's Textbook of Rheumatology. 9th ed. Philadelphia, PA: Saunders Elsevier; 2013:1221.

CASE 46-3, QUESTION 2: What is an appropriate initial treatment strategy for T.K.?

Empiric antibiotic therapy does not reduce the risk of recurrence of reactive, and antibiotics are therefore not routinely recommended for uncomplicated cases. As is the case with T.K., an active documented infection such as Chlamydia in the urine or bacteria in the stool in gastrointestinal infections should receive treatment. It is possible that by the time arthritis presents stool cultures would be negative following a gastrointestinal foodborne illness. Those with documented Chlamydia trachomatis infection and their partners should be offered antibiotics (azithromycin 1 g orally as a single dose or doxycycline 100 mg twice/day for 7 days).[37,38] Further information on appropriate antibiotic therapy for the infections that can cause reactive arthritis can be found in the chapters in Section 14: Infectious Disease. Although some studies have reported success of prolonged use of combination antibiotics specifically in reactive arthritis following Chylmadia,[37,40] a meta-analysis evaluating the efficacy of antibiotics in the routine treatment of reactive arthritis concluded that they did not induce remission, but this issue remains uncertain due to heterogeneity of the studies.[41] Antibiotic use was associated with a 97% increase in gastrointestinal side effects.[41]

Oral nonsteroidal anti-inflammatory drugs may be useful for pain control and inflammation, but there is no evidence that they affect arthritis itself or shorten the clinical course.[37]

CASE 46-3, QUESTION 3: Three weeks later, T.K. reports that he has had resolution of the low-grade fever and any pain on urination but that he is not receiving adequate pain relief in his knee. He complains that it is limiting his activities. What additional therapies can be considered?

Because T.K. is still experiencing pain in his left knee, an intra-articular corticosteroid injection, or oral corticosteroids if more joints are affected, may be considered. Intra-articular corticosteroid injections do not have as dramatic or as sustained a response as in those with rheumatoid arthritis. However, they may be helpful for the treatment of pain and swelling. For those who suffer from a persistence of reactive arthritis, a disease-modifying antirheumatic drug such as sulfasalazine is well tolerated and possibly effective at a dose of 1 g 2 or 3 times daily. Consideration may be given to start DMARD therapy earlier in the course of the disease if a patient is having a recurrence of reactive arthritis or is HLA-B27 positive.[36] Aggressive and unremitting reactive arthritis may be treated with immunosuppressants, if it is confirmed the initial infection is cleared. In severe cases, where patients fail to achieve adequate relief with prior therapies, antitumor necrosis factor (TNF)-α treatment may be considered. Limited evidence is available and is discussed in the literature primarily through case reports. Physical therapy modalities may be an integral part of management to improve mobility and strength and to prevent stiffness and deformities if needed.[36–38]

Polymyositis and Dermatomyositis

Polymyositis (PM) and dermatomyositis (DM) are idiopathic autoimmune and inflammatory disorders of unknown etiology involving a number of voluntary skeletal muscles simultaneously. PM and DM are characterized by the presence of inflammatory myopathies. In addition, DM involves specific skin manifestations, whereas PM does not.[42,43] Dermatomyositis is also associated with an increased risk of malignancies. Fifteen percent of patients over 40 years of age have a preexisting malignancy or will develop one in the future.[44] Therapy is aimed at reducing the risk of respiratory failure, renal failure, and cardiomyopathy as potential complications of either disorder. A proportion of patients (approximately 11%– 40% of those with DM) will meet the diagnostic criteria for other CTDs. This overlap syndrome is thought to occur more frequently in men than in women (9:1 ratio). Patients with myositis are likely, reported in 11% to 40%, to have another connective tissue disease (e.g., scleroderma, SLE, rheumatoid arthritis, and sarcoidosis).[45]

PM typically presents between the ages of 50 and 60 years and is rarely seen in children. DM exhibits a bimodal distribution and affects adults between the ages of 45 and 65 years, as well as a peak in children aged 5 to 15. African-Americans are at an increased risk for these disorders, and both women and men (2:1) are affected.[45] For dermatomyositis, the prevalence in the United States is 5.8 cases/100,000 individuals. In the United Kingdom, the prevalence among children was reported as 3.2/million. Polymyositis is reported in the United States at a prevalence of 9.7/100,000, but it should be noted that polymyositis is a diagnosis that is more difficult to make due to overlap of symptoms with other myopathies.[46] The prevalence is thought to lie between 50 and 100 cases/million for idiopathic inflammatory myopathies.[42]

There is no clear cause of either disorder, and both are thought to involve immune-mediated processes triggered by environmental factors (autoimmune or viral) in genetically susceptible individuals. DM is thought to be a complement-mediated microangiopathy in which inflammatory infiltrates arise owing to ischemic phenomena. In patients with PM, muscle fibers may be damaged by cytotoxic CD8 T lymphocytes. Infectious agents implicated as causative factors include coxsackievirus, influenza virus, retroviruses, cytomegalovirus, and Epstein–Barr virus. Various autoantibodies are found in up to 60% of patients. Expression of a genetic-specific HLA subtype (HLA DRB1-03 in whites and HLA DRB1-14 in Koreans) places individuals from certain ethnic groups at an increased risk. Exposure to UV radiation also increases the risk of developing DM.[45]

Symptom onset for both PM and DM is insidious, and patients initially complain of muscle weakness of the trunk, shoulders, hip girdles, upper arms, thighs, neck, and pharynx. These patients usually report increasing difficulties in everyday tasks requiring the use of proximal muscles such as getting up from a chair, climbing stairs, stepping onto a curb, lifting objects, and combing hair. Frequent falls, fatigue, malaise, weight loss, shortness of breath, and low-grade fever are also often present. Classification of PM and DM can be accomplished by assessing the presence or absence of certain characteristics unique to the condition. Polymyositis rarely affects children as compared to dermatomyositis that occurs more frequently. Specifically, they are largely separated by the involvement of cutaneous changes and calcinosis in dermatomyositis. Specific manifestations seen in DM are described in Table 46-7.[47] At present, no diagnostic criteria for PM and DM have been clearly defined and validated. After other conditions (e.g., human immunodeficiency virus (HIV) infection, lichen planus, SLE, psoriasis, or drug-induced causes) have been considered and ruled out, diagnosis may be confirmed by generally accepted criteria including the presence of proximal muscle weakness, elevated serum concentrations of skeletal muscle enzymes (e.g., creatine kinase, lactate dehydrogenase), myopathic changes on electromyography, evidence of inflammation on muscle biopsy, and skin rash (for DM only).[45,47,48]

CASE 46-4

QUESTION 1: J.A. is a 45-year-old white woman with a history of PM. She was initially diagnosed 1 year ago and was treated with high-dose oral prednisone for 3 months, at which time an attempt to taper the corticosteroid to the lowest effective dose was initiated. Since that time, J.A. has not been able to completely stop corticosteroid therapy without the recurrence of muscle weakness, which affects her ability to perform activities of daily living. In the past 3 months, her symptoms have progressed to the point where she was titrated back to his initial high-dose prednisone regimen in an attempt to gain adequate relief. At this point, J.A. and her primary-care physician are considering alternative options for symptom control. What is a reasonable pharmacotherapeutic option to recommend that may provide J.A. with symptom relief?

The initial and long-term goals of therapy are to improve muscle weakness, thereby improving the activities of daily living. The clinical course of both PM and DM varies in severity from mild to more severe progressive disease. Those with mild forms of the disease usually have a rapid response to therapy, whereas those with more severe or slowly progressive forms of the disease are more likely to not respond to treatment; this is a marker for a poor prognosis. As demonstrated in J.A.'s case, initial therapy with high-dose corticosteroids (e.g., 1 mg/kg) is used, followed by slow taper depending on response to therapy. The approach may include a switch to alternate day dosing during the taper or a 10% reduction in dose every 2 weeks.[45–49] In severe cases, it may be preferred to begin with intravenous corticosteroid therapy with methylprednisolone for 3 to 5 days at a dose of 1,000 mg. Patients who respond early to high-dose corticosteroids typically respond better to corticosteroid-sparing agents (e.g., methotrexate, azathioprine) in the future. J.A.'s failure to respond to corticosteroids should prompt further investigation for other possible pathologic processes including muscular dystrophy, hypothyroidism, or malignancy-associated myopathy. Should those investigations yield no conclusive results, J.A. may be offered methotrexate, azathioprine, mycophenolate mofetil, or cyclosporine as recommended immunosuppressants and steroid-sparing agents if the disease is not controlled with corticosteroids alone, is rapidly progressive, or presents with extramuscular involvement. If the complication of interstitial lung disease is present, cyclophosphamide or tacrolimus may be considered. If a patient does not have a sufficient response to corticosteroids, then intravenous immune globulin can be given over 2 to 5 days.[42,45,49] Ongoing trials will evaluate the potential use of other immune-modulating therapies.

Table 46-7

Cutaneous Manifestations of Dermatomyositis

Pathognomonic Skin Lesions of DM

1. Gottron papules: papules having a violaceous hue overlying the dorsal lateral aspect of interphalangeal and/or metacarpophalangeal joints. When fully formed, these papules become slightly depressed at the center which can assume a white, anthropic appearance. Associated telangiectasia can be present.
2. Gottron signs: symmetric macular violaceous erythema with or without edema overlying the dorsal aspect of the interphalangeal/metacarpophalangeal joints, olecranon processes, patellae, and medial malleoli.

Highly Characteristic Skin Lesions of DM

1. Periorbital violaceous (heliotrope) erythema with or without associated edema of the eyelids and periorbital tissue.
2. Grossly visible periungual telangiectasia with or without dystrophic cuticles.
3. Symmetric macular violaceous erythema overlying the dorsal aspect of the hands and fingers (where it can track the extensor tendon sheaths), extensor aspects of the arms and forearms, deltoids, posterior shoulders and neck (the shawl sign), V-area of anterior neck and upper chest, central aspect of the face and forehead.

Compatible Skin Lesions of DM

1. Poikiloderma vasculare atrophicans (poikilodermatomyositis) circumscribed violaceous erythema with associated telangiectasia, hypopigmentation, hyperpigmentation, and superficial atrophy most commonly found over the posterior shoulders, back, buttocks, and V-area of the anterior neck and chest.
2. Calcinosis cuts.

CASE 46-4, QUESTION 2: What preventive health measures may be offered to J.A. to augment her pharmacotherapeutic treatment regimen?

Supportive therapies such as bed rest, physiotherapy, warm baths, and moist heat applications to the affected areas can improve muscle stiffness. If oral lesions are present, irrigation of these lesions with warm saline solution is helpful. Preventive health measures for those experiencing either disorder include application of sunscreen, osteoporosis prevention, minimizing aspiration risk in patients with esophageal dysmotility, and physical therapy or customized exercise in patients with muscle weakness.[45] Although there has been previous concern to not further damage muscle, appropriate exercises including passive range of motion exercises and aerobic and resistance exercises have shown benefit.[44] Female patients placed on teratogenic immunosuppressants should discuss contraception, when appropriate.

Contraception

Shareen Y. El-Ibiary

	CORE PRINCIPLES	CHAPTER CASES
1	Contraceptive choice is based on several factors that include formulation, hormone content, effectiveness, side effect profile, cost, accessibility, past medical history, medication use, privacy of use, prevention of sexually transmitted infections (STIs), and return to fertility time.	**Case 47-1 (Question 1)**
2	Combined hormonal contraceptive (CHC) agents are a combination of estrogen and progestin. They are available in a variety of formulations that include a combination of estrogen and progestin (oral tablet, vaginal ring, and transdermal patch). CHCs may be classified by estrogen content into high dose (50 mcg of ethinyl estradiol), low dose (30–35 mcg of ethinyl estradiol), and very low dose (10–25 mcg of ethinyl estradiol), and can vary in cycle length (e.g., 21, 24, or 84 days of active hormone). Combined oral contraceptives (COCs) can be further classified by hormone content into monophasic, biphasic, triphasic, and quadriphasic.	**Case 47-1 (Questions 3–5, 7),** **Table 47-3**
3	CHCs have benefits aside from pregnancy prevention that include treatment of acne, hirsutism, premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD), and endometrial cancer; menstrual cycle regulation; and prevention of ovarian cancer and functional ovarian cysts.	**Case 47-2 (Questions 1–3)**
4	Breakthrough bleeding, nausea, acne, and weight gain are among the most commonly reported side effects in women taking hormonal contraceptives. Risks and side effects may be linked to estrogenic, progestogenic, or androgenic properties of hormonal contraceptives.	**Case 47-2 (Questions 4–8),** **Case 47-3 (Question 1),** **Table 47-4**
5	There are risks associated with CHCs and contraindications for use in some women. Estrogen-containing contraceptives should be avoided in women who are 35 years or older and smoke more than 15 cigarettes/day, and should have uncontrolled hypertension, history of gallbladder disease, stroke, migraines with aura, cardiovascular disease, and history of thromboembolic events.	**Case 47-1 (Question 2)**
6	Progestin-only contraceptives are alternative agents for women with contraindications to CHCs. Progestin-only contraceptives vary in	**Case 47-3 (Questions 2–6)**

	formulations that include oral tablet, depot and subcutaneous injection, and subdermal implant. Common side effects include weight gain, acne, mood changes, and irregular menses.	
7	Effectiveness of hormonal contraceptives is in part based on proper use and counseling. Patients need to understand how to use the contraceptive, what to do for mishaps (e.g., missed dose, vaginal ring falls out, transdermal patch falls off), and when to use a backup method. Directions for missed doses of progestin-only contraceptives vary from those for COCs.	**Case 47-1 (Question 6, 7), Case 47-3 (Questions 2–6)**

8	Concomitant use of certain drugs may increase or decrease the levels of hormonal contraceptive agents. In particular, antibiotics and hepatic inducers may decrease the effectiveness of CHCs. Progestin-only contraceptives or nonhormonal contraceptives including backup methods may be alternatives in these cases.	**Case 47-1 (Question 8), Table 47-5**
9	Intrauterine devices (IUDs) or intrauterine systems (IUSs) are available in two formulations (copper IUD and levonorgestrel IUS) and are best for long-term pregnancy prevention. To avoid the risk of pelvic inflammatory disease, the products should be used in women involved in a monogamous relationship.	**Case 47-3 (Question 7)**
10	Some nonhormonal contraceptives include diaphragms, condoms, and spermicides. Male and female condoms are the only contraceptive products that also provide protection against STIs.	**Case 47-4 (Questions 1, 2)**
11	Timing is a key for emergency contraception (EC) to be effective. It is best taken as soon as possible after unprotected sexual intercourse but may be effective up to 120 hours after coitus. Emergency contraception can be in the form of high-dose progestin pills, high-dose estrogen and progestin pills (known as Yuzpe method), selective progesterone receptor modulator (SPRM), or copper IUD.	**Case 47-4 (Question 3)**
12	Medical abortion generally consists of mifepristone or methotrexate (to stop development of the pregnancy), or both, in combination with misoprostol (to induce uterine contractions and expel the pregnancy).	**Case 47-4 (Question 4)**

EPIDEMIOLOGY

The world population is greater than 7.3 billion people.[1] In the United States, there are approximately 325 million people, and there is one birth every 8 seconds and 1 death every 12 seconds. This results in an increase in one person every 13 seconds.[1]

Contraception is currently an issue worldwide. Preventing unintended pregnancy is an important goal of contraceptive use, particularly in countries where population control is a goal. Economic implications play a role as well. Data from 2008 to 2011 show an estimated 45% of pregnancies in the United States were unintended, and of these, 42% resulted in abortions.[2] Proper use and understanding of contraceptives is important for preventing unintended pregnancies.

HORMONAL CONTRACEPTION BACKGROUND AND PHARMACOLOGY

Hormonal contraceptives include combinations of estrogens and progestins known as combination hormonal contraceptives (CHCs) or progestin-only contraceptives. Estrogens prevent the development of the dominant follicle by suppressing follicle-stimulating hormone (FSH) secretion and stabilize the endometrial lining to minimize breakthrough bleeding (see Chapter 50, Disorders Related to the Menstrual Cycle, for more information about the menstrual cycle).[3] Progestins prevent ovulation by suppressing luteinizing hormone (LH) secretion. They may work in combination with estrogen in CHCs such as combination oral contraceptives (COCs), the contraceptive patch, and the contraceptive ring, or alone in formulations such as the progestin-only pill (POP), depot intramuscular or subcutaneous injection, subdermal implant, and as part of intrauterine systems. Progestin-only contraceptives hamper the transport of sperm through the cervical canal by thickening cervical mucus and causing alterations in the endometrial lining (so that it is not favorable for implantation) and in the fallopian tubes (affecting ovum transport).

COMBINATION HORMONAL CONTRACEPTIVES

Patient Evaluation

CASE 47-1

QUESTION 1: S.F., a healthy 33-year-old woman, presents to the clinic stating she is getting married soon and would like birth control pills as a method of contraception. She does not have children but would like to start a family in a year or two. Her past medical history is noncontributory other than occasional headaches for which she takes ibuprofen 200 mg by mouth (PO) as needed.

Vital signs: weight, 128 lb; height, 5 feet 4 inches
Blood pressure, 122/72 mm Hg
Heart rate, 85 beats/minute
Temperature, 98.6°F
Social history: smokes one pack/day, denies alcohol
Family history: sister gestational diabetes, mother hypertension, father unknown
Which factors are important in the selection of a contraceptive agent for S.F.?

There are several factors that affect selection of a contraceptive. Among them is effectiveness in preventing pregnancy. It is important to determine the importance of pregnancy prevention for S.F. and choose a method based on this information. For example, patients taking teratogenic medications or those with underlying medical conditions in which pregnancy may not be desired will require a highly effective birth control method or multiple methods. Others may not desire a pregnancy, but for a variety of reasons an unintended pregnancy may be more acceptable.

The effectiveness of contraceptive methods depends on the mechanism of action, availability (e.g., prescription required), patients' concurrent medications, past medical history, and acceptability (e.g., side effects, ease of use, adherence, cost, and religious and social beliefs). Any or all of these factors can account for the discrepancy between the lowest failure rate observed for 1 year

in clinical trials (perfect-use failure rate) and the actual failure rate in users (typical-use failure rate) and should be taken into account when selecting a method of contraception (Table 47-1).[3] Return to fertility time is also an important factor to consider. Some contraceptive methods allow a woman to conceive shortly after discontinuation, whereas others may delay fertility longer. S.F. indicated she would like to have children in the near future. Given her age of 33 (fertility decreases more rapidly after age 30) and desire for future pregnancy, it would be best to select a product with a faster return to fertility.[4] However, other factors to consider when selecting a contraceptive agent for S.F. include contraindications and risks for her that may indicate one method over another. A combined hormonal contraceptive (CHC) is used commonly in women and may be appropriate for S.F. once all factors are considered.

Contraindications to Combined Hormonal Contraceptive Use

CASE 47-1, QUESTION 2: Are CHCs an appropriate form of contraception for S.F.? What contraindications to CHC therapy must be considered?

To determine whether any contraindications or precautions exist, the clinician should first obtain baseline health information from S.F. such as past medical history, social history, and family history (Fig. 47-1).[5] The World Health Organization has developed medical eligibility criteria to identify appropriate contraception for patients with specific conditions. In 2010, the Centers for Disease Control and Prevention adopted those guidelines for recommendations in the United States and updated them in 2016 (See http://who.int/reproductivehealth/publications/family_planning/MEC-5/en/. Accessed June 11, 2017) html for the WHO Medical Eligibility Criteria and CDC link).[6,7] Most data regarding contraindications are based on COCs, but the conclusions are applied to all CHCs (e.g., vaginal ring and transdermal patch).

Table 47-1

Percentage of Women Experiencing an Unintended Pregnancy During the First Year of Typical Use and the First Year of Perfect Use of Contraception and the Percentage Continuing Use at the End of the First Year: United States

Method	% of Women Experiencing an Unintended Pregnancy Within the First Year of Use		% of Women Continuing Use at 1 Year[c]	Relative Cost[k]
	Typical Use[a]	Perfect Use[b]		
Chance[d]	85	85	—	
Fertility awareness-based methods	24	—	47	None
Standard Days method[e]		5		
TwoDay method[e]	—	4	—	
Ovulation method[e]	—	3	—	
Symptothermal[e]	—	0.4	—	
Withdrawal	22	4	46	
Spermicides[f]	28	18	42	$–$$
Barrier methods				
Sponge				$$
Parous women	24	20	42	
Nulliparous women	12	9	57	
Diaphragm[g]	12	6	57	$$$
Condom[h]				$
Female (Reality)	21	5	41	
Male	18	2	43	
Hormonal contraceptives				
Injectable MPA	6	0.2	56	$$$[l]
Pill				
Progestin only	9	0.3	67	$$-$$$
Combined	9	0.3	67	$$-$$$
Transdermal patch	9	0.3	67	$$-$$$
Vaginal ring	9	0.3	67	$$-$$$

IUD/IUS	—	—	—	$$$$[l]
Copper	0.8	0.6	78	
Levonorgestrel	0.2	0.2	80	
Female sterilization	0.5	0.5	100	$$$$[m]
Male sterilization	0.15	0.10	100	$$$$[m]
Emergency contraceptive pills				$$$
Treatment initiated within 72 hours after unprotected intercourse reduces the risk of pregnancy by at least 75%.[i]				
Lactational amenorrhea method				None
LAM is a highly effective, temporary method of contraception.[j]				

[a] Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, fertility awareness-based methods, the diaphragm, the male condom, the oral contraceptive pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth corrected for underreporting of abortion; see the source for the derivation of estimates for the other methods.

[b] Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. See the table source for the derivation of estimates for the other methods.

[c] Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

[d] The percentages becoming pregnant in first year are based on data from populations in which contraception is not used and from women who cease using contraception to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentages who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

[e] The ovulation and TwoDay methods are based on evaluation of cervical mucus. The Standard Days method avoids intercourse on cycle days 8 through 19. The Symptothermal method is a double-check method based on evaluation of cervical mucus to determine the first fertile day and evaluation of cervical mucus and temperature to determine the last fertile day.

[f] Foams, creams, gels, vaginal suppositories, and vaginal film.

[g] With spermicidal cream or jelly.

[h] Without spermicides.

[i] ella (ulipristal) is labeled for 120 hours after unprotected intercourse. Plan B One-Step, Next Choice One Dose, MyWay, Take Action, Aftera, EContra Ez, and After Pill are levonorgestrel products specifically marketed for emergency contraception. The labeling for these products says to take the pill within 72 hours after unprotected intercourse. Research has shown that all of the brands listed here are effective when used within 120 hours after unprotected sex. Research has shown that both pills can be taken at the same time with no decrease in efficacy or increase in side effects and that they are effective when used within 120 hours after unprotected sex. The Food and Drug Administration has in addition declared the following 19 brands of oral contraceptives to be safe and effective for emergency contraception: Ogestrel (one dose is two white pills), Nordette (one dose is four light-orange pills), Cryselle, Levora, Low-Ogestrel, Lo/Ovral, or Quasence (one dose is four white pills), Jolessa, Portia, Seasonale or Trivora (one dose is four pink pills), Seasonique (one dose is four light-blue-green pills), Enpresse (one dose is four orange pills), Lessina (one dose is five pink pills), Aviane or LoSeasonique (one dose is five orange pills), Lutera or Sronyx (one dose is five white pills), and Lybrel (one dose is six yellow pills).

[j] However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breast-feeding is reduced, bottle feeds are introduced, or the baby reaches 6 months of age.

[k] $ up to $10/item, $$ up to $50/unit, $$$ up to $80/unit, $$$$ more than $80/unit (These are approximate costs and

may vary based on location of purchase and patient insurance.).

[l] Administration or clinic costs not included. Initial cost of product reported but over time similar to $$ cost (e.g., injectable MPA 150 mg/mL suspension one syringe approximately $95, but works for 3 months making its monthly cost similar to COCs or POPs which range from $20 to $45/pack generic, and copper IUD and levonorgestrel IUS may cost more initially but will work for up to 10 years and 5 years, respectively).

[m] Initial cost for procedure but over time may be more cost-effective than other products used frequently (e.g., monthly contraceptives, condoms, or spermicides).

IUD, intrauterine device; IUS, intrauterine system; LAM, lactational amenorrhea method; MPA, medroxyprogesterone acetate.

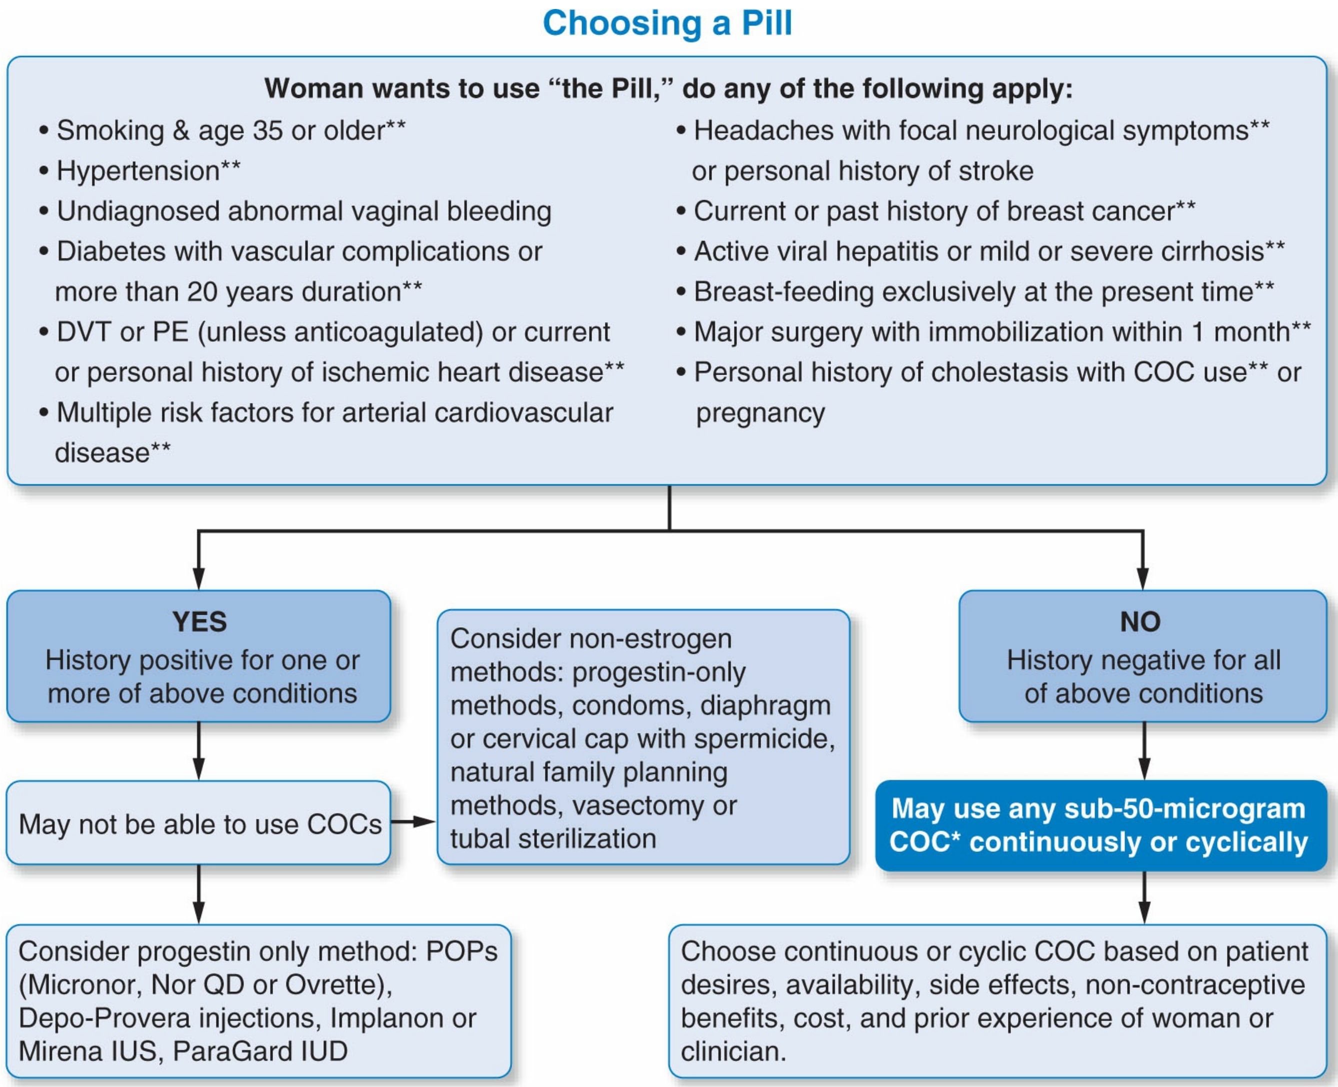
Accessed August 25, 2017; http://americanpregnancy.org/preventing-pregnancy/diaphragm/. Accessed June 11, 2017; https://www.plannedparenthood.org/learn/birth-control/cervical-cap. Accessed June 11, 2017.

CIGARETTE SMOKING AND USE OF CHCS

S.F. should be strongly encouraged to stop smoking (see Chapter 91, Tobacco Use and Dependence). Women who are 35 years of age or older and smoke 15 or more cigarettes/day should not use CHCs as a method of contraception. Although S.F. is not yet 35, she is smoking one pack/day (20 cigarettes). In her case, many clinicians would not prescribe CHCs. Although S.F. currently does not have any medical problems that would preclude her from using CHCs, she should be informed that CHCs should not be prescribed for her in 2 years if she continues to smoke. In addition, S.F. should be informed that smoking may decrease fertility and has adverse effects on birth outcomes, which is important given her plans to start a family in the near future.

CARDIOVASCULAR DISEASE

An increased risk of cardiovascular death in women who use COCs has been reported in several studies.[8–11] One study reported that in women who do not smoke or use COCs, the risk of cardiovascular death is 0.59/100,000 women younger than 35 years and 3.18/100,000 women at least 35 years of age. Among nonsmokers, using COCs increased the risk to 0.65/100,000 and 6.21/100,000 women younger than 35 years or at least 35 years of age, respectively. For COC users who smoke, the risk is 3.3/100,000 women younger than 35 years and 29.4/100,000 women at least 35 years of age.[12] The increase in mortality is concentrated in smokers of 35 years and older.



Choosing a Pill
Woman wants to use "the Pill," do any of the following apply:
• Smoking & age 35 or older**
• Hypertension**
• Undiagnosed abnormal vaginal bleeding
• Diabetes with vascular complications or more than 20 years duration**
• DVT or PE (unless anticoagulated) or current or personal history of ischemic heart disease**
• Multiple risk factors for arterial cardiovascular disease**
• Headaches with focal neurological symptoms** or personal history of stroke
• Current or past history of breast cancer**
• Active viral hepatitis or mild or severe cirrhosis**
• Breast-feeding exclusively at the present time**
• Major surgery with immobilization within 1 month**
• Personal history of cholestasis with COC use** or pregnancy
YES
History positive for one or more of above conditions
May not be able to use COCs
Consider non-estrogen methods: progestin-only methods, condoms, diaphragm or cervical cap with spermicide, natural family planning methods, vasectomy or tubal sterilization
Consider progestin only method: POPs (Micronor, Nor QD or Ovrette), Depo-Provera injections, Implanon or Mirena IUS, ParaGard IUD
NO
History negative for all of above conditions
May use any sub-50-microgram COC* continuously or cyclically
Choose continuous or cyclic COC based on patient desires, availability, side effects, non-contraceptive benefits, cost, and prior experience of woman or clinician.

- The World Health Organization and the Food and Drug Administration both recommend using the lowest dose pill that is effective. All combined pills with less than 50 mcg of estrogen are considered "low-dose" and are effective and safe.

- There are no studies demonstrating a decreased risk for deep vein thrombosis (DVT) in women on 20-mcg pills. Data on higher dose pills have demonstrated that the less the estrogen dose, the lower the risk for DVT.

- All COCs lower free testosterone. Class labeling in Canada for all combined pills states that use of pills may improve acne.

- To minimize discontinuation due to spotting and breakthrough bleeding, warn women in advance, reassure that spotting and breakthrough bleeding become better over time.

*The package insert for women on Yasmin and Yaz states [Berlex-2001]: "Yasmin is different from other birth control pills because it contains the progestin drospirenone. Drospirenone may increase potassium. Therefore, you should not take Yasmin if you have kidney, liver or adrenal disease, because this could cause serious heart and health problems. Other drugs may also increase potassium. If you are currently on daily, long-term treatment for a chronic condition with any of the medications below, you should consult your healthcare provider about whether Yasmin is right for you, and during the first month that you take Yasmin, you should have a blood test to check your potassium level: NSAIDs (ibuprofen [Motrin®, Advil®], naproxen [Naprosyn®, Aleve®, and others] when taken long-term and daily for treatment of arthritis or other problems]; potassium-sparing diuretics (spprionolactone and others); potassium supplementation; ACE inhibitors (Capoten®, Vasotec®, Zestril® and others); Angiotensin-II receptor antagonists (Cozaar®, Diovan®, Avapro® and others); heparin."

**These are conditions that receive a WHO:3 or a WHO:4 (based on WHO Medical Eligibility Criteria for Contraceptive Use, 5th ed. 2015, Category 3—A condition in which theoretical or proven risks usually outweigh the benefit of contraceptive method use, Category 4—A condition that represents an unacceptable health risk if contraceptive method is used).

Figure 47-1 Choosing a pill. ACE, angiotensin-converting enzyme; COC, combined oral contraceptive; DVT, deep venous thrombosis; IUD, intrauterine device; IUS, intrauterine system; NSAIDs, nonsteroidal anti-inflammatory drugs; PE, pulmonary embolism; POP, progestin-only pill. (Adapted with permission from Zieman M,

Hatcher RA. Managing Contraception. Tiger, GA: Bridging the Gap Communications; 2012: Figure 23.1.)

Several studies have focused on the effect of COCs on serum lipoprotein concentrations because of the association between lipoproteins and atherosclerotic cardiovascular disease.[13–15] High levels of total cholesterol (TC), triglycerides (TG), low-density lipoprotein (LDL) cholesterol, and very low density lipoprotein (VLDL) cholesterol serum concentrations are associated with the risk of developing atherosclerotic circulatory diseases, whereas high-density lipoprotein (HDL) cholesterol has an inverse relationship. Apolipoprotein levels also affect atherosclerotic risk (e.g., elevations in apolipoprotein increase risk).

Patients taking COCs may be more likely to experience a myocardial infarction (MI) than nonusers.[16] The risk is higher with higher doses of estrogen and especially if the patient is a smoker or has hypertension. It is not clear whether certain types of progestin are more likely to cause MI than others.[10,17] Combined oral contraceptive users may also be at a slightly higher risk of stroke, but some data are conflicting.[16] Those at highest risk of stroke are smokers, patients with hypertension, and patients older than 35 years.

S.F. and her fiance should understand that the risk of adverse cardiovascular effects may be increased with CHC use, but the absolute risk is still very low no matter which product is used. S.F.'s cigarette smoking, however, is a much more significant risk factor for MI in combination with a CHC product.

MIGRAINES AND STROKE

Ischemic stroke is more likely to occur in CHC users with a history of migraines and is thought to be caused by the estrogen component. The risk is further elevated in women who have migraines with aura or among those who smoke.[3,18] Women experiencing migraines without aura should use CHCs with caution or avoid use if they smoke and are at least 35 years of age.[7,19] Clinical experience indicates that women who have increasing migraine attacks with CHCs are not likely to improve when the product is changed to one with a different hormone balance. Headaches or migraines may start with initiation of CHCs (see Case 47-2, Question 6); however, if a patient experiences a migraine with aura while taking CHCs, she should discontinue the product and switch to a nonestrogen method.[18,19] Evidence does not show an increased stroke risk with progestin-only contraceptives, and these agents may be used in women with risk factors for stroke.[19]

S.F. does have a history of occasional headaches but does not have a history of migraines with aura. Therefore, she is still a candidate for CHCs but should be informed of the increased risk of stroke from cigarette smoking.

THROMBOEMBOLIC EVENTS

Combined hormonal contraceptives contribute to thromboembolic events by several mechanisms. Estrogens increase coagulability and thereby increase the possibility of clot formation. Although they have been shown to significantly increase some clotting factors, other studies have shown no changes or decreases in prothrombotic factors.[13,15] Long-term COC use is associated with an increased platelet count and increased platelet aggregation similar to that seen late in pregnancy; this is generally thought to be caused by the estrogen component. More recent data showing increased thrombosis rates in users of third-generation progestins (desogestrel and gestodene [not available in the United States]) suggest that progestin may also have a role in thromboembolism risk.[20]

The baseline risk of venous thromboembolism (VTE) in women is low, at 1 case/10,000 person-years, but increases from 3 to 4 cases with COC use.[21] The best studies looking at thromboembolism in COC users found that most users have a twofold-to-sixfold increased risk of having superficial or deep venous thrombosis or pulmonary embolism (PE).[20] Patients requiring emergency major surgery while taking COCs are more prone to VTE than nonusers. The risk of venous thrombosis does not seem to be associated with duration of COC use or past COC use. A greater risk is associated with ethinyl estradiol (EE) doses greater than 35 mcg.[20]

Women with a mutation in clotting factor V (also called factor V Leiden) or a deficiency in protein C, protein S, or antithrombin are more likely to experience a VTE with COCs than women without a hereditary prothrombotic defect.[22] Women with factor V Leiden using COCs have a 30-fold increase in VTE compared with women without the mutation.[22]

The minimal risk of thrombosis associated with CHCs in the general population does not justify the cost of routine screening for deficiencies and mutations in the coagulation system; however, if a patient has a family history of thrombosis, then measurement of antithrombin III, protein C, activated protein C resistance ratio, protein S, anticardiolipin antibodies, prothrombin G mutation, factor V Leiden, and homocysteine levels should be considered.[5]

Whether third-generation progestins (desogestrel, gestodene) are associated with a higher risk of VTE relative to other progestins is controversial.[20] It was believed that the risk of thrombosis with third-generation progestins would be lower than that with other progestins because they have more beneficial effects on HDL. However, most studies that compared the risk of thrombosis with third-generation progestins to second-generation progestins found that desogestrel and gestodene are associated with a greater VTE risk. A concern regarding fourth-generation progestin has emerged as well with drospirenone. Studies show that among new users products with drospirenone increase VTE risk compared with other products; adjusted hazard ratio 95% CI is 1.77 (1.33–2.35). An increase in VTE was also found when compared with levonorgestrel-containing products; adjusted hazard ratio 95% CI: 1.57 (1.13–2.18). Among all users, the risk of VTE was also increased with drospirenone use; adjusted hazard ratio 95% CI is 1.74 (1.42–2.14), and adjusted hazard ratio 95% CI is 1.45 (1.15–1.83) when compared with levonorgestrel.[23,24] In December 2011, FDA voted that the benefits outweigh the risks of using drospirenone products and recommended labeling changes to highlight VTE risks.[24] In April 2012, the FDA also published a safety communication regarding a possible increased risk of thrombosis with drospirenone-containing products.[25] Although the risk may be increased, the overall rate of thrombosis is still low. All patients using CHCs should be counseled about the VTE warning signs (Table 47-2).[5]

S.F. does not have a history of clotting disorders or previous clots. Therefore, she is still a candidate for CHCs. Her smoking status, however, puts her at higher risk for VTE. If she experiences a VTE while taking CHCs, a progestin-only method or nonhormonal contraceptive method should be recommended and the CHC discontinued.

HYPERTENSION

Combined hormonal contraceptives appear to increase blood pressure. Small studies have found systolic blood pressure to increase by 7 to 8 mm Hg and diastolic blood pressure to increase by 6 mm Hg in normotensive or mildly hypertensive women, and these women may have poorer blood pressure control.[26,27] Other studies have shown differing results on whether women with hypertension who use COCs are more likely to suffer an MI than nonusers.[6,28] A small study of adolescent women showed similar systolic and diastolic blood pressures in users versus nonusers.[29]

The underlying mechanisms for CHC-induced hypertension may be sodium and water retention and increased renin activity.[30,31] Hypertension secondary to COCs may develop slowly during 3 to 36 months and may not decline for 3 to 6 months after COC discontinuation.[32] Women with controlled hypertension may attempt a trial of CHCs with blood pressure monitoring; however, progestin-only contraceptives have not been shown to increase blood pressure and may be preferable for women with uncontrolled hypertension.[26]

Table 47-2

Pill Early Danger Signs (ACHES)[3]

Signals	Possible Problem
Abdominal pain (severe)	Gallbladder disease, hepatic adenoma, blood clot, pancreatitis
Chest pain (severe), shortness of breath, or coughing up blood	Blood clot in lungs or myocardial infarction
Headaches (severe)	Stroke, hypertension, or migraine headache
Eye problems: blurred vision, flashing lights, or blindness	Stroke, hypertension, or temporary vascular problem
Severe leg pain (calf or thigh)	Blood clot in legs

S.F.'s blood pressure is not elevated at 122/72 mm Hg. Therefore, she is still a candidate for CHCs. If her blood pressure were greater than 140/90 mm Hg, a nonhormonal method or a progestin-only contraceptive would be a preferred form of contraception.

HEPATOTOXICITY

Combined oral contraceptives have been associated with benign liver tumors, hepatic adenomas, and liver cancer.[3,33] The risk of liver cancer is low, and COCs are thought to cause only a modest increase in risk.[33,34] A European study found a small, statistically significant increase in the risk of liver cancer in women without cirrhosis and without hepatitis B or C, which are the types of women that usually use COCs. In this study, COC use in these women increased the risk of liver cancer by 1 case/1.5 million woman-years.[34] S.F. should be reassured that it is very unlikely for her to develop benign or malignant liver tumors associated with COC use.

DIABETES

Generally, low-dose COCs do not alter glucose tolerance.[15,35] Women with a history of gestational diabetes like S.F's sister and those with a strong family history of diabetes in parents or siblings are at greater risk for COC-induced glucose intolerance.[26] Combined oral contraceptives have complex effects on carbohydrate metabolism. Progestins decrease and estrogens increase the number of insulin receptors on the cell membrane. Progestins also may alter insulin receptor affinity. The different progestins in CHCs have different propensities to induce glucose intolerance. Desogestrel seems to have the best glucose values compared with other progestins, but insulin results are not consistent.[35]

Results of one controlled, randomized, prospective study showed no adverse effect on carbohydrate or lipid metabolism in women with a history of gestational diabetes after 6 to 13 months of low-dose CHC use.[36] Both the users and nonusers showed a significant and similar deterioration in glucose tolerance with an overall prevalence of 14% impaired glucose tolerance and 17% diabetes mellitus. The authors concluded that low-dose COCs could be prescribed safely and that serum lipids and glucose tolerance should be monitored closely, regardless of contraceptive choice.

For women with diabetes, the World Health Organization recommends avoiding COCs if they have been diabetic for more than 20 years or they have end-organ damage such as retinopathy, neuropathy, or nephropathy.[6] For women without diabetes, CHC use may protect against developing diabetes. One large prospective, observational study found that women who used COCs had lower fasting glucose levels and lower odds of developing diabetes.[37]

S.F.'s sister having a history of gestational diabetes does not preclude S.F. from using a CHC at this time. Preferably, S.F. should start on a low-dose CHC.

GALLBLADDER DISEASE

The incidence of gallstones has been reported to increase with COC use; however, conflicting data exist. Estrogens and progestins may contribute to bile stasis and gallstones by reducing cholesterol clearance and altering bile acid composition.[38] The incidence of gallbladder disease has been reported to increase during the first year of use but then to decline steadily to a rate lower than that of control women.[39] Conversely, in another large study, long-term COC users experienced slightly lower rates of gallbladder disease than nonusers.[40] In addition, another study found that women who had ever used COCs were not more likely to have symptomatic gallstones, but current and long-term users were. An analysis of 482 women with benign gallbladder disease from the Oxford/Family Planning Association contraception study concluded that it is unlikely that COCs cause gallbladder disease.[41]

The newer COCs with lower progestin and estrogen concentrations should have little effect, if any, on gallstone formation in normal patients. Women who are obese, young, or long-term users of COCs may be the most likely to develop gallstones. At this time, this is not a concern of S.F. in starting COCs.

Combined Oral Contraceptives

CASE 47-1, QUESTION 3: S.F. has decided to quit smoking. Based on her past medical history, she is a candidate for CHCs and indicates she wants to start a COC. Which COC should be selected for her?

Selecting a COC for S.F. can be confusing because of the multitude of products available, the lack of studies directly comparing products, and health insurance medication formulary restrictions. The failure rate of COCs ranges from 0.3% with perfect use to 9% with typical use (Table 47-1).[3]

The COCs are available in varying strengths of estrogens and progestins. Table 47-3[42–51] lists the brand name and generic COCs in the United States. Almost all COCs available in the United States contain the synthetic estrogen, EE. Doses of EE generally range from 10 to 50 mcg with 10- to 25-mcg formulations considered very low dose, 30- to 35-mcg formulations, low dose, and 50-mcg formulations, high dose. Mestranol, another estrogen available in the United States and used internationally, is an inactive prodrug that is hepatically metabolized to EE. Mestranol 50 mcg has approximately the same activity as EE 35 mcg.[3] Estradiol valerate is a third estrogen available in one oral formulation. The formulation of estradiol valerate 2 to 3 mg with 2 to 3 mg of dienogest was compared against EE 20 mcg with levonorgestrel 100 mcg in clinical trials.[47,52]

The COCs also contain one of the following progestins: ethynodiol diacetate, desogestrel, dienogest, drospirenone, levonorgestrel, norethindrone, norethindrone acetate, norgestimate, and norgestrel (a mixture of dextronorgestrel and levonorgestrel; dextronorgestrel appears to be progestationally inert compared with levonorgestrel).[3] Progestins differ significantly in their progestational potency and in the extent of their metabolism to estrogenic substances. Progestins have both estrogenic and antiestrogenic effects. Because the progestins have a chemical structure similar to that of testosterone, they also have varying degrees of androgenic activity (Table 47-3).[53] Minor structural changes in all of the progestins may lead to significant changes in their progestational, estrogenic, antiestrogenic, and androgenic activities, which may affect patients differently (Table 47-4).[3] Drospirenone is a unique progestin because it has antiandrogenic and antimineralocorticoid properties. Drospirenone is chemically similar to the potassium-sparing diuretic spironolactone, and therefore, may increase potassium levels. Drospirenone should be used with caution in patients using medications that can increase potassium levels (e.g., high-dose nonsteroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting enzyme [ACE] inhibitors, heparin, potassium-sparing diuretics, aldosterone antagonists, and angiotensin II blockers).[43]

Because no COC has been shown to be superior to the others, any COC with less than 50 mcg of EE can be used for patients who are COC candidates.[54] The information in Figure 47-1 may be used to select an initial COC for most patients and to change formulations when side effects necessitate an alternative choice.[6] Increased body weight (>70.5 kg) has been associated with increased COC failure.[55] If S.F. were heavier, a COC with a higher dose of EE (e.g., 35 mcg) would be a better option. Any pill containing less than 50 mcg EE can be used for S.F. because she is a healthy woman without medical complications or active medications.

Table 47-3

Oral Contraceptives and Relative Progestin, Estrogen, and Androgen Activities[42–51,53]

Ingredients	Brand Name Examples	Progestin Activity	Estrogen Activity	Androgen Activity	Unique Properties
Monophasic Formulations					
Levonorgestrel 0.1 mg/EE 20 mcg	Amethia Lo, Aubra, Aviane, Camrese Lo, Delyla, FaLessa, Falmina, Lessina, Levlite, LoSeasonique, Lutera, Orsythia, Sronyx	Low	Low	Low	Amethia Lo, Camrese Lo, and LoSeasonique contain 84 active pills and contain 7 pills of EE 10 mcg instead of placebos

Levonorgestrel 0.09 mg/EE 20 mcg	Amethyst	Low	Low	Low	Amethyst is a 1-year continuous formulation available in packs of 28 active pills
Norgestimate 0.25 mg/EE 35 mcg	Estarylla, Mono-Linyah, MonoNessa, Ortho-Cyclen, Previfem, Sprintec	Low	Intermediate	Low	
Norethindrone 0.5 mg/EE 35 mcg	Brevicon, Modicon, Necon 0.5/35, Nortrel 0.5/35, Wera	Low	High	Low	
Norethindrone 0.4 mg/EE 35 mcg	Blaziva, Femcon Fe, Gildagia, Ovcon-35, Philith, Vyfemla, Wymzya FE, Zenchent, Zenchent FE	Low	High	Low	Femcon Fe, Wymza FE, and Zenchant FE are chewable formulations and contain 7 pills of 75 mg ferrous fumarate instead of placebos
Levonorgestrel 0.15 mg/EE 30 mcg	Altavera, Amethia, Ashlyna, Camrese, Daysee, Chateal, Kurvelo, Levora, Introvale, Jolessa, Marlissa, Nordette-28, Portia, Quasence	Intermediate	Low	Intermediate	Introvale, Jolessa, and Quasense contain 84 active pills and 7 placebo pills. Amethia, Ashlyna, Camrese, and Daysee contain 84 active pills and 7 pills of EE 10 mcg instead of placebos
Norgestrel 0.3 mg/EE 30 mcg	Cryselle, Elinest, Low-Ogestrel	Intermediate	Low	Intermediate	
Norethindrone 1 mg/mestranol 50 mcg	Necon 1/50, Norinyl 1+50	Intermediate	Intermediate	Intermediate	
Norethindrone 1 mg/EE 35 mcg	Alyacen 1/35, Cyclafem 1/35, Dasetta 1/35, Necon 1/35, Norethin 1/35, Norinyl 1+35, Nortrel 1/35, Ortho-Novum 1/35, Pirmella 1/35	Intermediate	High	Intermediate	
Norethindrone acetate 1 mg/EE 20 mcg	Gildess 24 FE, Gildess 1/20, Gildess FE 1/20, Junel Fe 1/20, Junel 21 Day 1/20, Junel FE 24, Larin 24 FE, Larin 1/20, Larin FE 1/20, Loestrin 21 1/20, Loestrin Fe 1/20, Lomedia 24 FE, Microgestin Fe 1/20, Minastrin 24 FE, Tarina Fe 1/20	High	Low	Intermediate	“Fe” or “FE” contains 75 mg ferrous fumarate instead of placebos, and Gildess 24 FE, Junel FE 24, Larin FE 24, Lomedia FE 24, and Minastrin 24 FE have 24 active tablets
Norethindrone	Gildess 1.5/30, Gildess	High	Low	High	“Fe” contains 75 mg

acetate 1.5 mg/EE 30 mcg	FE 1.5/30, Junel 1.5/30, Larin 1.5/30, Larin FE 1.5/30, Loestrin 21 1.5/30, Loestrin Fe 1.5/30, Microgestin Fe 1.5/30				ferrous fumarate instead of placebos
Ethynodiol diacetate 1 mg/35 mcg EE	Kelnor 1/35, Zovia 1/35E	High	Low	Low	

Desogestrel 0.15 mg/EE 20 mcg	Azurette, Kariva, Kimidess, Pimtrea, Mircette, Viorele	High	Low	Low	Only 2 days of placebos, other 5 days contain EE 10 mcg
Desogestrel 0.15 mg/EE 30 mcg	Apri, Desogen, Emoquette, Enskyce, Ortho-Cept, Reclipsen, Solia	High	Intermediate	Low	
Ethynodiol diacetate 1 mg/EE 50 mcg	Zovia 1/50E	High	Intermediate	Low	
Norgestrel 0.5 mg/EE 50 mcg	Ogestrel	High	High	High	
Norethindrone 0.8 mg/EE 25 mcg	Generess Fe, Layolis Fe	No data	No data	No data	"Fe" contains 75 mg ferrous fumarate instead of placebos, and Generess Fe and Layolis Fe contain 24 active pills and 4 pills of ferrous fumarate, chewable formulation
Norethindrone 1 mg/EE 10 mcg	Lo Loestrin Fe, Lo Minastrin Fe	No data	No data	No data	Lo Loestrin Fe and Lo Minastrin Fe contain 24 active pills, 2 pills of 10 mcg EE, and 2 pills of 75 mg ferrous fumarate
Drospirenone 3 mg/EE 20 mcg levomefolate calcium 0.451 mg	Beyaz	No data	No data	None[a]	Provides folate supplementation, FDA-approved use for treatment of acne and PMDD, 24 active pills and 4 days of 0.451 mg of levomefolate calcium instead of placebos
Drospirenone 3 mg/EE 20 mcg	Gianvi, Loryna, Nikki, Vestura, YAZ	No data	No data	None[a]	Antimineralocorticoid properties, FDA-approved use for treatment of acne and PMDD, only 4 days of placebos

Drospirenone 3 mg/EE 30 mcg/levomefolate calcium 0.451 mg	Safyral	No data	Intermediate	None[a]	Provides folate supplementation, 21 active pills, and 7 days of 0.451 mg of levomefolate calcium instead of placebos
Drospirenone 3 mg/EE 30 mcg	Ocella, Syeda, Yasmin, Zarah	No data	Intermediate	None[a]	Antimineralocorticoid properties
Biphasic Formulations					
Norethindrone 0.5, 1 mg/EE 35 mcg	Necon 10/11	Intermediate	High	Low	
Triphasic Formulations					
Norgestimate 0.18, 0.215, 0.25 mg/EE 25 mcg	Ortho Tri-Cyclen Lo	Low	Low	Low	
Norgestimate 0.18, 0.215, 0.25 mg/EE 35 mcg	Ortho Tri-Cyclen, Tri-Estarylla, Tri-Linyah, TriNessa, Tri-Previfem, Tri-Sprintec	Low	Intermediate	Low	FDA-approved use for treatment of acne
Levonorgestrel 0.05, 0.075, 0.125 mg/EE 30, 40, 30 mcg	Enpresse, Levonest, Myzilra, Trivora	Low	Intermediate	Low	
Norethindrone 0.5, 1, 0.5 mg/EE 35 mcg	Aranelle, Leena, Tri-Norinyl	Low	High	Low	
Norethindrone 0.5, 0.75, 1 mg/EE 35 mcg	Alyacen7/7/7, Cyclafem 7/7/7, Dasetta 7/7/7, Necon 7/7/7, Nortel 7/7/7, Ortho-Novum 7/7/7, Pirmella 7/7/7	Intermediate	High	Low	
Norethindrone 1 mg/EE 20, 30, 35 mcg	Tilia Fe, Tri- Legest 21, Tri-Legest Fe 28	High	Low	Intermediate	Estrophasic (estrogen content changes), FDA-approved use for treatment of acne, “Fe” contains 75 mg ferrous fumarate instead of placebos
Desogestrel 0.1, 0.125, 0.15 mg/EE 25 mcg	Caziant, Cesia, Cyclessa, Velivet	High	Low	Low	
Quadriphasic Formulation					
Dienogest 0, 2, 3, 0 mg/estradiol valerate 3, 2, 2, 1	Natazia	No data	Low	No data	Has 2 placebo pills, 2 pills with 3 mg of estradiol valerate only, 5

mg					pills with 2 mg of dienogest and 2 mg of estradiol valerate, 17 pills with 3 mg of dienogest and 2 mg of estradiol valerate and 2 pills of 1 mg estradiol valerate
Levonorgestrel 0.15, 0.15, 0.15, 0 mg/EE 20, 25, 30, 10 mcg	Quartette	Intermediate	Low	Intermediate	Has 91 pills, 42 contain 0.15 mg of levonorgestrel with 20 mcg of ethinyl estradiol, 21 pills contain 0.15 mg of levonorgestrel with 25 mcg of ethinyl estradiol, 21 pills contain 0.15 mg of levonorgestrel with 30 mcg of ethinyl estradiol, 7 pills contain 10 mcg of ethinyl estradiol
Progestin Only					
Norethindrone 0.35 mg	Camila, Errin, Jolivette, Micronor, Nor-QD, Nora-BE, Deblitane, Heather, Jencycla, Norlyroc, Sharobel	Low	None	Low	No placebos, 28 days of active pills

[a] Preclinical studies have shown that drospirenone has no androgenic, estrogenic, glucocorticoid, antiglucocorticoid, or antiandrogenic activity.

EE, ethinyl estradiol; FDA, US Food and Drug Administration; PMDD, premenstrual dysphoric disorder.

LENGTH OF ACTIVE HORMONE: 21-, 24-, OR 28 DAY

The COCs are available in a variety of cycle lengths. The most common is the 28-day pack that contains 21 days of active pills (pills that contain estrogen and progestin) followed by 7 days of placebo pills. Some newer products contain 24 days of active pills followed by 4 days of placebo. Combined hormonal contraceptives with 4 days of placebo may shorten menses and minimize the hormonal withdrawal side effects (e.g., headaches, mood changes) that some women experience during the placebo week.[56]

It is also possible that efficacy is improved; however, this has not been proven in clinical trials.

The 21-day pill packs contain only the active pills. Most patients are instructed to take one pill daily for 21 days and then take nothing for 1 week. Many clinicians prefer the use of 28-day pill packs to minimize confusion; the patient takes one pill daily regardless of whether it is an active or placebo pill. After taking the last pill of a 28-day pack, the patient should begin a new pack the next day. However, when continuous ovarian suppression is indicated to treat estrogen-dependent disorders such as endometriosis, the 21-day cycle products are preferred to facilitate taking active pills continuously. Alternatively, the placebo pills could be removed from 28-day cycle packs. S.F. will not be taking COCs continuously, so a 24- or 28-day pack is recommended.

MULTIPHASIC ORAL CONTRACEPTIVES

CASE 47-1, QUESTION 4: Should S.F. start a monophasic or multiphasic COC? What are the advantages and disadvantages of the monophasic versus multiphasic COC?

COCs have varying amounts of hormones in the active pills, which can be divided in phases that include monophasic, biphasic, triphasic, or quadriphasic (Table 47-3).

Monophasic COCs contain the same dose of estrogen and progestin in each active pill throughout the pill pack, whereas multiphasic COCs have varying amounts of hormones. Because of metabolic and physiologic effects related to the progestin component of COCs, multiphasic products were initially formulated to contain less progestin overall. Some products, however, are now marketed with varying amounts of estrogen to reduce the overall exposure to estrogen or to minimize estrogen withdrawal side effects (e.g., norethindrone/EE [Tri-Legest 21 and Tri-Legest Fe 28]).

A biphasic formulation usually contains a certain amount of progestin and estrogen for the first half of the cycle, then a different amount for the second half, and then a week of placebos. Triphasic formulations have a different amount of hormones for each of the 3 weeks of active pills. No studies, however, show a superiority of one triphasic over another or compared with monophasics. The reduced progestin content is desirable for women with complaints of progestin-associated side effects (e.g., increased appetite, acne, weight gain) or women with cardiovascular disease or metabolic abnormalities.[3] Women with side effects related to progestin deficiency (e.g., late-cycle bleeding) or conditions necessitating progestin dominance (e.g., benign breast disease) may do better with monophasics. Recently, a quadriphasic COC (Natazia) became available, and it contains four different amounts of hormones throughout the pill pack.[47] Advantages of the product remain to be seen, but it may help decrease hormone withdrawal side effects and intermenstrual bleeding.

One drawback associated with triphasic and quadriphasic COC use is the confusion caused by the different-colored pills in each of the three different phases, making the missed-dose instructions more complicated. Monophasics are preferred for women who will be taking COCs continuously (i.e., skipping the placebo pills) because of the same weekly hormone content.

Other unique formulations include Mircette (see Table 47-3 for generic names), which is classified more appropriately as monophasic because the hormone content is consistent throughout the 21-day cycle like other monophasic formulations, but sometimes referred to as biphasic because it does not contain 7 days of placebos. It provides a unique regimen containing 21 days of 0.15 mg of desogestrel plus 20 mcg of EE, then only 2 days of placebo, followed by 5 days of 10 mcg of EE alone.[50] The patient does not need to take missed 10-mcg EE doses or use a backup method when those specific pills are missed. Adding low-dose estrogen for 5 days during the typical placebo week helps minimize breakthrough bleeding with this product and may be useful for patients who have estrogen-deficiency symptoms such as headaches during the hormone-free week. Because S.F. has not been on a CHC before and does not have a history of side effects associated with COCs, she may be started on any of the COC formulations.

EXTENDED CYCLE

CASE 47-1, QUESTION 5: S.F. has heard that she can skip the placebos from her pill pack to have fewer menses each year. She is interested in this approach. Is this a reasonable option for S.F.?

Continuous- or extended-cycle COC regimens (i.e., skipping the placebo pills and taking no break between pill packs, thus having no menses) are often prescribed in women with underlying conditions including anemia, dysmenorrhea (less cramps with fewer menstrual cycles), menorrhagia (heavy menstrual bleeding), and endometriosis (to decrease hormone fluctuations that affect endometrial tissues).[5] In addition, for convenience and lifestyle reasons, many women prefer to take COCs continuously to minimize the number of menstrual periods. Regardless of the reason, any woman who is a candidate for CHCs can use them continuously.

Any CHC (e.g., pill, patch, vaginal ring) may be used continuously; however, from the COCs, monophasic pills are recommended because of the consistent hormone content throughout the cycle. Any duration of continuous pill use is acceptable, but many providers recommend that patients take the active pills for 3 to 4 months (3–4 pill packs) and then stop COCs for 2 to 7 days. Alternatively, providers may prescribe COCs that are specifically packaged for continuous use (e.g., Amethyst, Camrese Lo). Patients should be informed that continuous COC use usually results in more breakthrough bleeding or spotting than traditional COC dosing regimens, with up to 41% of women experiencing some form of irregular bleeding in the first few months of the one-year regimen.[51]

Concerns raised with extended-use regimens include harmful effects on the endometrium; however, one study showed no harmful changes to the endometrium with extended cycles.[57] Long-term side effects of the extended regimens are still being studied. If breakthrough bleeding continues beyond 6 months of continuous COC use, a pelvic examination may be considered. If S.F. is willing to tolerate more irregular bleeding during the first 6 months of continuous COC use, then the extended-cycle regimen may work for her.

Patient Instructions

CASE 47-1, QUESTION 6: What instructions should be given to S.F. about her COC?

WHEN TO START ORAL CONTRACEPTIVES

S.F. should start the first cycle of COCs according to the manufacturer’s package instructions or according to one of the following recommendations:[3]

1. Quick start: Take the first COC tablet as soon as possible regardless of cycle day.[5
2. Day 1 start: Take the first tablet in the COC pack on the first day of menses.
3. Sunday start: Take the first tablet in the COC pack on the first Sunday after the beginning of menstruation. If menses begins on Sunday, start that day.

The quick start method is not described in COC package inserts; however, this method is used by family planning providers.[58,59] The quick start method can minimize the confusion that many patients have about when to start their first pack and can increase adherence. Also, the quick start method provides contraceptive protection sooner and would, therefore, likely lower the risk of unintended pregnancy. More research on and awareness about this method are needed for it to be used routinely by all healthcare providers.

WHEN TO USE A BACKUP METHOD OF CONTRACEPTION

Some clinicians recommend that a woman use an alternative method of contraception for the entire first COC cycle. Others believe that alternative methods of contraception are unnecessary if the COC is started on or before the fifth day of the menstrual cycle. Most COC package inserts with the exception of Natazia (estradiol valerate/dienogest) state that a backup method of contraception (e.g., male or female condoms, spermicides, diaphragms) is not necessary if patients use the day 1 start method.[4] If patients use the Sunday or quick start methods, backup contraception should be used for the first week of the COC cycle. A backup method is also recommended when doses are missed, as described in the following section. S.F. has decided to use the quick start method, so she will need to use another method of contraception for her first week of COC use.

COC ADMINISTRATION AND MISSED DOSE INSTRUCTIONS

S.F. should take her COC at the same time each day. Nausea may be prevented or alleviated by taking the dose at bedtime or with food. The best time to take COCs depends on the patient. The optimal time for S.F. is the time when she will have the fewest problems remembering to take her pill each day.

If a woman forgets to take one pill, she must take it as soon as she remembers and refer to the patient instructions in the package insert for further information.[3] Some unique formulations such as estradiol valerate/dienogest (Natazia) have more specific recommendations based on the cycle day missed. If she is taking Natazia, she should be referred to the package insert for information (see http://www.natazia.com), as the advice varies from that listed below.

For the majority of COCs, most manufacturers recommend that if she forgets to take one pill, she should take two pills on the day she remembers (e.g., if she forgets her pill on Monday, she should take two pills on Tuesday). Then she should take the remaining pills as usual. A backup method of contraception is not necessary. If she misses two pills in a row in week 1 or 2 of her pack, she must take two pills on the day she remembers and two pills the next day. She should use an alternative method of contraception for 7 days after missing the pills and may consider emergency contraception.

If a woman misses two pills in a row during the third week (for day 1 starters), she must discard the rest of the pack, start a new pack on that same day, and use an alternative contraceptive method for 7 days. For Sunday starters, she should keep taking one pill every day until Sunday, then start a new pack on Sunday. She must use an alternative method of contraception for 7 days after missing the pills and may consider emergency contraception. She may miss her menstrual period this month.

If a woman misses three or more pills in a row during the first 3 weeks (for day 1 starters), she must discard the rest of her pack, start a new pack that same day, and use an alternative method of contraception for 7 days; Sunday starters should keep taking one pill every day until Sunday, start a new pack on Sunday, and use an alternative method of contraception for 7 days after missing the pills, and they may consider emergency contraception. Women may not have a menstrual period this month. If two pills are missed from a low-dose COC (less than EE 30 mcg), some references suggest following the instructions as if three pills were missed.[3] Other references and organizations may cite different recommendations. The recommendations described here are recommended by manufacturers.

CONTRACEPTIVE PATCH AND RING

CASE 47-1, QUESTION 7: S.F. returns to the clinic 3 months later and is very concerned about getting pregnant because she has trouble remembering to take her pill each day. She wants an effective contraceptive method but is wondering whether other dosage formulations are available. She also indicates concern about high doses of estrogen because she has heard high doses of estrogen can lead to blood clots. She wants the lowest possible dose. What do you tell her?

Contraceptive Patch

The contraceptive patch has an estimated failure rate of 0.3% with perfect use and 9% with typical use (Table 47-1). The contraceptive patch (Ortho Evra, Xulane) contains 6 mg of norelgestromin and 750 mcg of EE. It was originally formulated to transdermally deliver 150 mcg of norelgestromin and 20 mcg of EE daily into the systemic circulation; however, higher doses of ethinyl estradiol are now thought to be delivered (see below).[60] The patch is a 1.75-inch square with rounded corners and is beige and thin. One patch is applied each week for three consecutive weeks for a total of three patches used, followed by 1 week with no patch. The day of the week the patch is applied is called the patch change day. Then this cycle is repeated. Menses should begin during the patch-free week. If a woman wants to avoid menses, the patch-free week may be skipped by applying a new patch on week 4 for an extended-use regimen.

The contraceptive patch may be worn on the buttock, abdomen, upper torso, or upper outer arm.[60] The patch should not be applied to the breasts to prevent direct administration of estradiol to the breast tissue. To minimize irritation from the adhesive, S.F. should rotate the patch application sites and not apply the patch to the same location within each month. When applying the patch, S.F. should select the application site and be sure it is clean and dry. She should press firmly on the patch for 10 seconds and trace her finger around the edge of the patch to be sure it adheres securely to the skin. The patch should stay attached during usual activities, including exercising, swimming, and bathing. If the patch falls off and is off less than 24 hours, she should reapply it or apply a new one as soon as possible, and her patch change day will stay the same. No backup contraception is needed. If the patch is off for more than 24 hours, she should start a new cycle of patches, and she will have a new patch change day. She should use backup contraception for 1 week.

The patch may be started using the quick, Sunday, or day 1 start method, and the recommendations for backup contraception are the same as described earlier with CHCs.[60] If S.F. forgets to start the first patch of a new cycle, she should apply it as soon as she remembers. This day will become her new patch change day, and she should use backup contraception for 1 week. If she forgets to change the patch for 1 or 2 days during week 2 or 3, she should apply a new patch as soon as she remembers. This becomes her new patch change day. No backup contraception is needed. If she forgets to wear the patch for more than 2 days, she should start a new cycle as soon as she remembers. She will need to use backup contraception for 1 week and will have a new patch change day.

The effectiveness of the patch is reduced in patients weighing more than 90 kg and should not be used alone for prevention of pregnancy in these women.[60] S.F. does not weigh more than 90 kg, which does not preclude her from using this method.

The most common side effects reported with the patch are breast tenderness, headache, application site reaction, and nausea. Most risks and benefits with the contraceptive patch are thought to be similar to COCs. One notable difference is the rate of VTE. A small pharmacokinetic trial found that overall monthly serum levels of EE are significantly higher in patch users compared with ring or COC users.[61] With the patch, the peak levels of estrogen are lower, but the steady-state concentrations are higher. It has been noted that the patch provides 60% more ethinyl estradiol than an oral 35-mcg tablet.[60] This raised concern that the patch may have a higher incidence of VTE than the other methods; however, it is controversial. One study found no difference in the rate of nonfatal VTE in patch versus COC users, whereas another study found a doubling of VTE risk in patch users compared with COC users.[62–65] The package insert for the transdermal patch was modified to include this new information.[63] Future studies may find that there are other differences in certain risks or benefits between the patch and pill. Given the higher amounts of EE and controversy surrounding VTE with the transdermal patch, this may not be the most appropriate method for S.F. based on her concerns of VTE associated with COC use.

Contraceptive Ring

The failure rate for the contraceptive ring is also 0.3% with perfect use and 9% with typical use (Table 47-1).[3] The contraceptive ring (NuvaRing) delivers 120 mcg of etonogestrel and 15 mcg of EE daily through the vaginal mucosa.[66] The ring is flexible, transparent, and has a diameter of just over 2 inches. The ring is inserted vaginally and kept in place for 3 weeks in a row. After 3 weeks, the ring is removed for 1 week, and then a new ring is inserted (see http://www.spfiles.com/pinuvaring.pdf). For extended use, the ring-free week may be skipped by inserting a new ring on week 4.

The ring may be placed anywhere in the vagina, so S.F. does not need to worry about its exact position.[66] To insert the ring, she should compress it so the opposite sides of the ring are touching, and gently insert it into the vagina.

If she feels discomfort with the ring, it has probably not been inserted into the vagina far enough. Most women do not feel the ring once it is in place. To remove the ring, S.F. should grasp the ring between two fingers or hook one finger inside the ring and pull it out. Menses will usually begin within 3 days of removing the ring. If the ring slips out, it should be rinsed with lukewarm water and reinserted. If the ring is out for less than 3 hours, backup contraception is not needed. If the ring is out for more than 3 hours, backup contraception should be used for 1 week. According to the manufacturer, if the ring has been left in the vagina for longer than 3 weeks but no more than 4 weeks, S.F. should remove it, wait 1 week, then reinsert a new ring. The ring is formulated to contain approximately 35 days of medication but should not be promoted for use beyond 21 days.[66] If it has been in place for more than 4 weeks, she should remove it, confirm that she is not pregnant, reinsert a new one, and use backup contraception for 1 week.

The contraceptive vaginal ring should be inserted anytime during the first 5 days of the menstrual cycle or inserted using the quick start method.[3,66] Backup contraception should be used for the first week. When changing from the COC, S.F. should insert the ring within 7 days of the last active pill and no backup contraception is needed.

The ring is believed to have the same contraindications and precautions as COCs. The most common side effects with the ring are vaginal infections, irritation, and discharge; headache; weight gain; and nausea. Unlike the patch, the ring has not been shown to increase VTE risk or has reduced efficacy in obese women.[66] A study of 1,950 women using the contraceptive ring for 13 months found a high degree of patient satisfaction and adherence to the contraceptive method.[67] The ring provides the least amount of EE exposure when compared with other CHCs.[61] However, despite the lower levels of EE provided, one study has shown an increased risk of VTE with the use of the contraceptive vaginal ring when compared with levonorgestrel-containing contraceptives.[68] Though this study indicated a possible increase in VTE with the vaginal ring, the FDA has not required any labeling changes or communicated any safety issues with the vaginal ring. Given the good adherence rates and lower EE levels, the vaginal ring may be appropriate for S.F. if she is comfortable with the dosage form.

Drug Interactions

CASE 47-1, QUESTION 8: S.F. returns to the clinic 2 months later for a sore throat. She indicates that she is using the contraceptive vaginal ring.

Current vitals at clinic: weight, 132 lb; height, 5′4″
Blood pressure, 125/78 mm Hg
Heart rate, 97 beats/minute
Respiratory rate, 16 breaths/minute
Temperature, 101.1°F
Physical examination: head, eyes, ear, nose, and throat: tonsils 2+, bright red, soft palate erythematous
Laboratory test results: rapid streptococcal antigen test, positive

S.F.'s primary-care physician prescribes Augmentin 875 mg/125 mg (amoxicillin/clavulanate) twice daily by mouth for 10 days. Could this medication affect her contraception? What advice should be provided to S.F.? What other drug interactions are of concern with CHCs?

A variety of drugs may alter the levels of CHCs and in turn affect their efficacy (Table 47-5).[7,69–72] Currently, most data available regarding drug interactions are with COCs. However, as a precaution the potential drug–drug interactions observed with COCs are also applied to the other CHC dosage formulations (e.g., vaginal ring and transdermal patch).

ANTIBACTERIALS

The antibacterials rifampin and griseofulvin are known to cause contraceptive failure, as these products increase the metabolism of estrogen. For other antibacterials, the possible interaction is more complicated.

EE is conjugated in the liver, excreted in the bile, hydrolyzed by intestinal bacteria, and reabsorbed as active drug.[72] Antibacterials, by reducing the population of intestinal bacteria, interrupt the enterohepatic circulation of the estrogen, resulting in a decreased concentration of circulating estrogen. Theoretically, any antimicrobial with significant effects on intestinal bacterial flora could affect COC efficacy. Numerous reports of changes in bleeding patterns and contraceptive failure have been documented.[72] Cases of pregnancy in COC users taking antibiotics have been reported.[72–74] About 30 case reports of contraceptive failure with concomitant COC and antibiotic use have been published.[72] The antibacterials in the case reports include rifampin, ampicillin, penicillin G, tetracycline, and minocycline. In addition, surveys conducted on patients in clinics have revealed about 20 other cases of COC failure.[72] A major limitation of survey data is that it relies on patient reporting, which is often unreliable. Some believe that the probability of a clinically significant drug interaction between COCs and antibacterials is low and the CDC US Medical Eligibility Criteria does not recommend a need for alternative birth control methods while taking broad-spectrum antibiotics that do not affect hepatic enzymes.[7,74,75]

Table 47-5

Common Combined Oral Contraceptive (COC) Drug[a] Interactions[42,69–71]

Drugs That Increase Effect of CHCs or Side Effects of CHCs	Drugs/Herbals That Decrease the Effect of CHCs	Drugs That May Decrease the Effect of CHCs (controversial)	Metabolism or Clearance Altered by CHCs (levels of drug listed may either increase or decrease depending on patient)
Acetaminophen	Amprenavir	Amoxicillin	Acetaminophen
Ascorbic acid	Aprepitant	Ampicillin	Amprenavir
Atazanavir	Barbiturates	Ciprofloxacin	Antidepressants, tricyclic
Atorvastatin	Bexarotene	Clarithromycin	Benzodiazepines
Ginseng	Bosentan	Colesevelam	β-blockers
Indinavir	Carbamazepine	Doxycycline	Caffeine
Red clover[b]	Darunavir	Erythromycin	Clofibric acid
Rosuvastatin	Efavirez	Fluconazole	Corticosteroids
Tranexamic acid	Felbamate	Itraconazole	Cyclosporine
Voriconazole	Griseofulvin	Ketoconazole	Lamotrigine
	Isotretinoin	Metronidazole	Levothyroxine
	Lopinavir	Minocycline	Morphine
	Modafinil	Penicillins	Paclitaxel
	Mycophenolate mofetil	Phenylbutazone	Salicylic acid
	Nelfinavir	Ofloxacin	Selegiline
	Nevirapine	Tetracyclines	Tacrine
	Oxcarbazepine	Topiramate	Tacrolimus
	Phenobarbital		Theophyllines
	Phenytoin/Fosphenytoin		Tizanidine
	Pioglitazone		Valproic acid
	Primidone		Voriconazole
	Red clover[b]		Warfarin[c]
	Rifamycins		
	Ritonavir		
	Rufinamide		
	Saquinavir		
	St. John's wort		
	Tipranavir		

[a] Drug list is not all inclusive. Some drug interactions may exist that are not cited in this table.

[b] Indicates drug may have variable effect on CHC either increasing or decreasing effect.

[c] May decrease anticoagulant effect of warfarin, not warfarin drug levels.

CHC, combined hormonal contraceptive.

Source: Borgelt L et al., eds. Women's Health Across the Lifespan: A Pharmacotherapeutic Approach . Washington DC: American Society of Health Systems Pharmacists; 2010.

Numerous factors may affect the likelihood of an interaction: the hormonal content of the COC relative to the patient’s requirements, the dosage and duration of use of the interacting drug, variation in the patient’s response to bacterial flora alteration, and the fertility of the couple.[72] The number and complexity of these variables make prediction of outcome in a specific patient exceedingly difficult. Even if a drug produces a several-fold increase in unintended pregnancies in women taking COCs, the likelihood of pregnancy in a given patient still will be low. For patients who require long-term, low-dose tetracycline use for acne therapy (e.g., tetracycline 250 mg by mouth daily), it is unlikely to interfere with COC efficacy.[74] Alternatively, topical antibacterials often can control acne and are viable alternatives to oral medications.

A practical approach to managing patients taking COCs and antibacterials is to educate patients about the available data. To be conservative, S.F. should be advised to use backup contraception while taking the amoxicillin/clavulanate and to continue the backup method until her next menses occurs though this is controversial and the CDC Medical Eligibility Criteria does not call for it.[7] For other antibiotics that affect hepatic enzymes such as rifampin, isoniazid, and griseofulvin, backup contraception should be used while taking the medication and for 4 weeks after discontinuation of the antibiotics.[7]

HEPATIC ENZYME INDUCTION

Ethinyl estradiol is a substrate of cytochrome P-450 3A4 (CYP3A4), so drugs that induce CYP3A4 activity may decrease COC efficacy. In earlier years, COC efficacy was not decreased significantly by other drugs because of their high hormone content. Because the estrogen and progestin concentrations of COCs have gradually been decreasing, reports of menstrual irregularities (e.g., spotting) and unintended pregnancies attributable to drug interactions have been increasing.

Anticonvulsants such as carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, and topiramate are CYP3A4 inducers and are known to cause increased metabolism of COCs (see Chapter 60, Seizure Disorders).[76] Some studies have shown that another inducer of COC metabolism is St. John’s-wort.[77,78] Although drugs can influence COC efficacy, COCs also can affect the activity of other drugs. For example, COCs have been reported to decrease serum levels of lamotrigine and can affect seizure control; as well increased levels of lamotrigine have been reported after COC discontinuation.[79] Other drugs may increase the hormone levels of COCs (Table 47-5), increasing the risk of COC side effects (Table 47-4).

Unlike many drug classes that are carefully dosed to maintain a therapeutic range of monitored blood levels, contraceptive estrogen and progestin blood levels are obtained only in clinical drug studies. Therefore, patients are managed by monitoring side effects and by changes in menstrual patterns. Some prescribers suggest using a

50-mcg EE COC in patients taking interacting drugs, although others might recommend using an alternative method of contraception if drug interactions are an issue.

Noncontraceptive Benefits of Combined Hormonal Contraceptives

ACNE

CASE 47-2

QUESTION 1: D.S., a 20-year-old woman, presents to her primary-care physician for a yearly pelvic examination and also complains of moderate acne flares. She has tried a variety of treatments without resolution and is currently using only topical medications. She heard birth control pills can help acne, especially if it occurs right before her period. She also complains of fatigue most days of the month and mood changes, cravings, cramps, and bloating near the time of her period.

Vitals: weight, 118 lb; height, 5′3″
Blood pressure, 118/75 mm Hg
Heart rate, 86 beats/minute
Respiratory rate, 13 breaths/minute
Temperature, 98.6°F
Past medical history: acne (since age 16)
Social history: denies tobacco and alcohol use, not sexually active
Family history: older sister cervical dysplasia grade 2 (age 26), maternal grandmother breast (age 61) and ovarian cancer (age 68)
Allergies: no known drug allergies
Current medications: benzoyl peroxide 5% cream, apply topically twice daily
Benzoyl peroxide 2.5% wash, wash affected area twice daily
Retin-A micro 0.1%, apply topically twice a week as tolerated
Multivitamin with iron by mouth daily
Past medications: doxycycline 100 mg by mouth twice daily for acne, stopped because of vaginal yeast infections
Physical examination: unremarkable with the exception of moderate facial acne
Laboratory test results: white blood cells, $6.0 \times 10^3/\mu L$
Red blood cells, $3.9 \times 10^6/\mu L$
Hemoglobin, 10.8 g/dL
Hematocrit, 32%
Mean cell volume, 79 µL
Mean corpuscular hemoglobin concentration, 31 g/dL
Red blood cell diameter width, 15%

What effect, if any, would CHCs have on her acne? Does D.S. qualify for CHC treatment of acne, and if so, which COC would you recommend for D.S.?

Depending on the patient, a CHC may cause acne to appear, disappear, or significantly improve.[4] D.S. is interested in COCs. Four COC products (norethindrone acetate/EE [Tri-Legest 21 and Tri-Legest Fe 28], norgestimate/EE [Ortho Tri-Cyclen], and drospirenone/EE [YAZ, Beyaz]) are US Food and Drug

Administration (FDA)-approved for the treatment of moderate acne vulgaris in women at least 15 years old (at least 14 years old for Beyaz and YAZ), who have no known contraindications to CHCs, reached menarche, desire contraception, and have failed topical acne treatments (Tri-Legest 21, Tri-Legest Fe 28, and Ortho Tri-Cyclen). Most CHCs, however, improve acne mainly as a result of the estrogen component. Higher doses of estrogen may decrease acne by suppressing the activity of sebaceous glands, decreasing the production of androgens, and increasing the synthesis of sex hormone-binding globulin (SHBG). The SHBG binds androgens and thereby diminishes their effects.[80] Progestins with higher androgenic activity may be more likely to increase acne because they stimulate sebaceous glands to produce more sebum. Both desogestrel- and norgestimate-containing oral contraceptives are less androgenic, whereas drospirenone has antiandrogenic properties, thereby decreasing acne associated with androgenic activity.[81] D.S. is 20 years old, has reached menarche, and has not responded to different acne treatments, and she therefore is a candidate for COC therapy. Her acne appears to be hormonally mediated, particularly because it appears around the time of her menses. It is likely that D.S.'s acne should improve with COC use, particularly if she uses a formulation with higher estrogenic activity and low androgenic activity (e.g., Beyaz, Safyral YAZ, Yasmin, Ortho Tri-Cyclen, Ortho Tri-Cyclen Lo, Mircette, Tri-Legest 21; see Table 47-3).

MENSTRUAL CYCLE BENEFITS

CASE 47-2, QUESTION 2: D.S. has iron-deficiency anemia, likely attributed to heavy menses. Will a COC help reduce her menstrual bleeding or menstrual cramps?

COCs help regulate menstrual cycles and reduce monthly blood loss.[28] This may reflect the progressive thinning of the endometrium of COC users and the lack of irregular bleeding. Bleeding may be decreased the most by COCs that have a high ratio of progestin to estrogen because endometrial thinning is maximized.[53] Some COCs have iron pills instead of placebos, often denoted with "Fe" in the name (e.g., Tri-Legest Fe 28, Femcon Fe, Loestrin Fe, Lo Loestrin Fe). Others have folic acid (e.g., Beyaz, Safyral) but D.S. would likely benefit more from the formulations with iron. Another option would be to have D.S. take COCs continuously so she has fewer menses.

Dysmenorrhea, or painful menstruation, may be of unknown origin or may be attributable to endometriosis or uterine fibroids. Data suggest menstrual pain might decrease by 60% after the initiation of a COC.[3] A COC with decreased estrogenic and increased progestational activity may be the best at relieving dysmenorrhea (see Chapter 50, Disorders Related to the Menstrual Cycle).

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

CASE 47-2, QUESTION 3: D.S. also complains of PMS symptoms such as bloating and mood changes. What treatment approaches are appropriate? What other noncontraceptive benefits do CHCs have?

Premenstrual syndrome (PMS) is a cyclic occurrence of one or more symptoms before the onset of menses. Most women complain of at least one PMS symptom, which includes irritability, bloating, and depressed mood.[82] Premenstrual dysphoric disorder (PMDD) is a more severe form of PMS and has diagnostic criteria by the American Psychiatric Association. Premenstrual tension has been reported to be reduced in COC users, and other premenstrual symptoms seem to improve as well. Nevertheless, the effect of COCs on PMS symptoms is inconsistent and unpredictable, probably because PMS symptoms are neither consistent nor predictable.[83]

There may be augmentation of depression and mood swings by the progestational component, although the probability of this effect is low with a low-dose product (see Chapter 50, Disorders Related to the Menstrual Cycle, for further discussion of PMS). Some patients may also notice depressed mood during the hormone-free period, in which case a continuous-use COC may be helpful.

Two products, drospirenone/EE (YAZ, Beyaz), have the FDA-approved indication for treatment of symptoms of PMDD. Drospirenone/EE has been studied most extensively in patients with PMDD.[42] D.S. may try any CHC to help with her PMS symptoms; however, because YAZ and Beyaz have more data to show that they are effective for PMDD and acne, one of them may be the preferred initial product for her. In addition, both products are 24-day formulations, which may help minimize her menstrual bleeding and help her iron-deficiency anemia.

ENDOMETRIAL CANCER

Clinical data suggest that COCs protect against endometrial cancer. This effect continues for 20 years after the last pill.[83] The protection is directly related to duration of use and may persist for many years after discontinuation of the COC.[4] A meta-analysis of 11 studies showed a 56%, 67%, and 72% reduction in endometrial cancer risk after 4, 8, and 12 years of COC use, respectively.[84]

OVARIAN CANCER AND FUNCTIONAL OVARIAN CYSTS

The risk of developing functional ovarian cysts is decreased, preexisting cysts are more rapidly resolved, and surgery rates for ovarian masses are reduced in women taking COCs.[85,86] This is likely attributable to reducing ovulation, suppressing androgen production, or increasing progesterone levels.

Each year of COC use decreases the relative risk of developing ovarian cancer by 7% to 9%.[86] The risk reduction continues to be seen in women using COCs for more than 15 years and persists after discontinuation.[83] D.S. should be reassured that COC use may decrease her risk of ovarian cancer given that she has a positive family history.

Combined Hormonal Contraceptive Risks and Adverse Effects

Some patients may not be candidates for CHCs because of the risks and adverse effects associated with their use. Other patients may experience minor side effects with CHCs that may be managed by changing to a CHC with different types or doses of estrogen or progestin. All patients should be counseled on the most serious side effects, which include pulmonary embolism or VTE, hepatotoxicity, or visual disturbances (could be a sign of retinal and corneal changes in the eye) and stroke. A helpful acronym to remember when counseling is "ACHES" (Table 47-2),[3] which can be used to increase a patient's awareness of serious potential adverse effects that warrant immediate medical attention.

Other less severe adverse effects are listed in Table 47-4.[53] Most side effects resolve within 3 months of use. If a patient experiences adverse effects other than those described in "ACHES," (Table 47-2) she should be encouraged to continue the CHC for at least 3 months before switching to a different contraceptive.

BREAKTHROUGH BLEEDING, SPOTTING, AND AMENORRHEA

CASE 47-2, QUESTION 4: D.S. comes to the family planning clinic after taking EE 20 mcg/drospirenone 3 mg (YAZ) for 2 months. She had been started on YAZ to help with her acne. She feels her acne has improved but reports irregular menstrual bleeding during her last two menstrual cycles which occurs around the third week of the pill pack and requires a pad. What action should be taken to correct D.S.'s bleeding pattern?

Intermenstrual bleeding is a bleeding that occurs at times other than the regular menses timing. Intermenstrual bleeding that requires a pad or tampon is designated breakthrough bleeding, whereas a lesser amount of intermenstrual bleeding is called spotting. Intermenstrual bleeding is experienced by many women in the first months of starting COCs (30%–50%).[3] Intermenstrual bleeding may also occur if a patient is not adherent to her COCs or taking medications that decrease COC effectiveness (Table 47-5).

Most clinicians will recommend that patients continue the same COC for at least 3 months if breakthrough bleeding or spotting is the only complaint, because this complication usually resolves within 3 months.[3] Early-cycle intermenstrual bleeding, which usually starts before the 14th day of the menstrual cycle (or never ceases completely after menses), is usually caused by insufficient estrogen. Late-cycle intermenstrual bleeding, occurring after day 14, is usually attributable to insufficient progestational support of the endometrium. Another cause of intermenstrual bleeding is drug interactions (see Case 47-1, Question 8, for more information about drug interactions).

The balance between estrogen and progestin components in COCs determines its endometrial activity and, therefore, the likelihood of intermenstrual bleeding problems. It may be helpful to envision the estrogen component as the basic building blocks or "bricks" of the endometrium and the progestational component providing the mortar that holds the bricks together. The estrogenic activity of the progestin component increases the number of bricks, whereas its antiestrogenic activity decreases their numbers. If there are not enough bricks or mortar or if they are present in the wrong proportions, the wall will crumble and bleeding will occur (Table 47-3).

If D.S.'s intermenstrual bleeding continues late in her cycle after 3 months, another COC with the same estrogen activity, more progestin activity, and low androgen activity should be prescribed. Desogestrel 0.15 mg/EE 30 mcg (e.g., Apri, Reclipsen) would be a good choice because progestational activity would be increased and estrogenic activity would be maintained with minimal androgenic liability (Table 47-3). If D.S. had experienced intermenstrual bleeding early in the cycle after several months of use, she should be changed to a formulation with a higher ratio of estrogen to progestin such as norethindrone 0.4 mg/EE 35 mcg (e.g.,Ovcon-35, Femcon Fe, Balziva, Zenchent). For D.S., products with low androgenic activity should be selected because of her acne.

Intermenstrual bleeding may also be the sign of other health conditions such as cervical or uterine cancer. If a patient presents with intermenstrual bleeding and has not had a recent pelvic examination, a healthcare provider may perform an examination to rule out other possible causes of intermenstrual bleeding. D.S. recently had a normal pelvic examination 2 months ago. Given the timing of when she began her COCs, it is likely her intermenstrual bleeding is caused by her COCs.

Some patients experience amenorrhea (no menstrual bleeding) with CHCs. If this occurs, pregnancy should first be ruled out. If the patient is not pregnant and amenorrhea is acceptable to the patient, then the CHC need not be changed. But this does make it difficult for the patient to recognize whether she may become pregnant in the future.

NAUSEA

CASE 47-2, QUESTION 5: D.S. continues to have intermenstrual bleeding late in her cycle after 3 months of use and is placed on a new COC. Five days after starting norethindrone 0.4 mg/EE 35 mcg (e.g., Ovcon-35), D.S. calls with complaints of nausea. What counseling should the clinician provide to D.S.?

Nausea from COCs can generally be attributed to the estrogen component. To help alleviate nausea, D.S. can take her pill at bedtime rather than in the morning. Another alternative may be to take it with food or to try another COC with a lower estrogen strength or property. Ovcon-35 has a higher amount of EE as compared with YAZ (35 mcg of EE vs. 20 mcg of EE), which may be causing nausea to D.S. D.S. should be advised that nausea generally resolves within 3 months of use.

HEADACHE

CASE 47-2, QUESTION 6: Three months later, D.S. returns to the clinic for follow-up and states that she has daily headaches during her placebo week but not when she is taking active pills. How should she be managed?

Headache is a common complaint in women taking CHCs or COCs, as is the case with D.S. Women may notice headaches while taking active pills, which may be related to sensitivity of estrogen. Others may experience headaches during the placebo week as a result of the withdrawal of estrogen.[3] Women with migraines may find that their headaches either improve or worsen when CHCs are initiated.

Mild headaches may improve with time or if the woman is changed to a pill with less estrogen or progestin. Headaches that occur during the placebo week can be managed by trying desogestrel 0.15 mg/EE 10 to 20 mcg (e.g., Mircette, Kariva), which minimizes the estrogen withdrawal by having only 2 days of placebos, or by taking CHCs continuously (i.e., skipping placebo pills or the hormone-free week). Patients with severe headaches should discontinue CHCs and should be evaluated by their healthcare provider (see Contraindications above). D.S. is experiencing headaches during the placebo week, indicating withdrawal of estrogen as the cause. Skipping the placebo pills and using an extended-cycle regimen may help decrease D.S.'s headaches.

WEIGHT GAIN

CASE 47-2, QUESTION 7: During the same visit, D.S. states she is gaining weight and feels "bloated on and off" since starting the new birth control pill. What might be happening, and how should the clinician respond?

Weight gain associated with CHC use is another common concern for women. A Cochrane review of three trials concluded that available evidence was insufficient to determine an association between COCs and weight gain and also stated no large effect was seen.[87] If weight gain is a concern, a low-dose estrogen and low-dose progestin products should be considered. Cyclic weight gain is generally caused by the mineralocorticoid effects of EE-stimulating aldosterone receptors to retain sodium, causing water retention and bloating. Too much progestin may cause an increased appetite and noncyclic weight gain. Drospirenone with antimineralocorticoid properties opposes EE effects, resulting in less water retention and weight gain, and increases in appetite may not be as apparent. D.S. recently increased her estrogen dose, which may be causing the "on and off" bloated feeling and weight gain. She also stopped taking a drospirenone-containing product, which may be why she did not experience the effects of bloating and weight gain with the previous product. The clinician should explain that weight gain is a potential side effect associated with COC use and is likely related to the estrogen component. It is reasonable to consider an alternative COC because she is having estrogen withdrawal headaches and weight gain. Desogestrel 0.15 mg/EE 10 to 20 mcg (e.g., Mircette) has lower estrogen activity than norethindrone 0.4 mg/EE 35 mcg (e.g., Ovcon-35; Table 47-3), which may help to decrease the cyclic weight gain and headaches while still helping to control her acne. In addition, desogestrel 0.15 mg/EE 10 to 20 mcg retains high progestational activity to address D.S.'s previous breakthrough bleeding and has low androgenic activity that will likely help her acne.

BREAST CANCER, CERVICAL DYSPLASIA, AND CERVICAL CANCER

CASE 47-2, QUESTION 8: The medical history and physical examination of D.S. are negative for breast and cervical diseases, except for a history of breast cancer in her maternal grandmother and a history of cervical dysplasia in her sister. D.S. asks how COC use will affect her risk of breast cancer and cervical cancer.

There are conflicting data regarding the association of COC use and breast cancer. The reported overall lifetime risk of breast cancer in American women is 12% to 13%.[88] Older studies have indicated a possible link between COC use and breast cancer.[89–92] More recent studies suggest that COC use does not increase breast cancer risk even with long-term use (e.g., 10 years).[93,94] In addition, other studies concluded breast cancer rates in high-risk women with BRCA 1 and 2 mutations or strong family history of breast cancer did not increase with COC use.[95,96] The American Congress of Obstetricians and Gynecologists (ACOG) does not consider a family history of breast cancer (including BRCA 1 and 2) or benign breast disease a contraindication to COC use.[26]

COCs would not be expected to increase the risk of breast cancer in D.S. She should be instructed to perform monthly breast self-examinations and to return annually for a physical examination by her primary-care physician.

With regard to D.S.'s concern of cervical cancer, it is important to educate D.S. about the incidence of cervical cancer and its relation to COC use. The American Cancer Society estimates that more than 12,000 cases of invasive cervical cancer will be diagnosed in 2017 and more than 4,000 women will die of it.[97] Behavior, not genetics, is the usual cause of cervical cancer.

Women at highest risk for cancer are those who are positive for certain subtypes of human papillomavirus (HPV), who have certain sexual behaviors, who are immunosuppressed, or who smoke.[3] Sexual behaviors associated with cervical cancer include beginning sexual activity at a young age, having multiple male sexual partners, and having a male sexual partner who has had

---

multiple partners. Women at low risk for cancer are those who have two or fewer partners, whose partners use condoms, and who do not smoke.

Pooled data on cervical cancer risk from eight case–control studies found that oral contraceptive users positive for HPV were more likely to develop cervical cancer.[98] Women who had ever used oral contraceptives and those who had used oral contraceptives for more than 5 years were 1.5 and 3.4 times, respectively, more likely to develop cervical cancer. This is consistent with older studies that suggest that oral contraceptive users have an increased risk of developing or dying of cervical cancer. In contrast, a large cohort study conducted in England found no significant increase in deaths attributable to cervical cancer in women who had ever used COCs.[99]

Epidemiologic comparisons of the prevalence of cervical cancer in oral contraceptive users versus nonusers often are difficult to interpret because yearly medical examinations and regular Pap smears of COC users result in early detection and treatment of precancerous lesions. Three vaccines for HPV are available for women aged 9 to 26 years. Because D.S. is 20 years old, she may be a candidate for the HPV vaccine (see Chapter 64, Vaccinations). D.S. may use COCs, should be encouraged to have regular Pap smears, and should be counseled on the behaviors that put her at risk for cervical cancer and the risks and benefits of the HPV vaccine.

USE DURING PREGNANCY AND BREAST-FEEDING

CASE 47-3

QUESTION 1: P.K., a 35-year-old woman, comes to clinic stating that she recently took a home pregnancy test that reported a positive result. Her last menstrual period (LMP) was 9 weeks ago. She would like to confirm the results and discuss the effects of her current medications on her unborn baby.

Vitals: weight, 143 lb; height, 5′6″
Blood pressure, 128/82 mm Hg
Heart rate, 97 beats/minute
Respiratory rate, 16 breaths/minute
Temperature, 98.6°F
Past medical history: history of abnormal menses, initiated on COC therapy to help regulate
Medications: desogestrel 0.15 mg/EE 30 mcg (Reclipsen)
Laboratory test results: blood test, qualitative human chorionic gonadotropin >25 mIU/mL

P.K. was started on desogestrel 0.15 mg/EE 30 mcg (Reclipsen) extended regimen 3 months ago because of a history of abnormal menstrual periods. Unknowingly, she became pregnant in the first month and continued her COC for two cycles, and is now 8-week pregnant. What can you tell P.K. about the possible effects of CHC use on her unborn child?

The fact that CHCs were classified as pregnancy category X (contraindicated, fetal risks clearly outweigh maternal benefit) is very misleading.[100] Although older, poorly designed studies found an association between COC use and cardiac or limb anomalies, newer data suggest that CHC use does not substantially increase the risk of anomalies over that expected in other uneventful pregnancies.[4]

Although a CHC should not be started in a woman who might possibly be pregnant, P.K. should be instructed to stop using her COC and be reassured that the risks to her fetus from the use of a low-dose CHC during the first trimester are likely minimal, while also informing her no drug is without risk and she should follow up with her obstetrician.

CASE 47-3, QUESTION 2: P.K. plans to breast-feed her infant and begin some types of contraception after her discharge from the hospital. Her past experience with condoms and concurrent spermicidal foams or gels resulted in itching and burning. She indicates she would like a contraceptive that would be suitable for long-term use while breast-feeding. What contraceptives are best for her while she is breast-feeding?

P.K. may use CHCs 6 weeks after she has her baby even if she is breast-feeding, although it is preferable for her to use a progestin-only method.[26] The ACOG recommends waiting at least 6 weeks before starting any estrogen-containing contraceptive regardless of breast-feeding status. By this time, the increased risk of thrombosis that occurs during pregnancy should be reduced to baseline. For non-breast-feeding women, a progestin-only contraceptive may be used immediately postpartum and 6 weeks postpartum if solely breast-feeding and in some cases 3 weeks postpartum if partially breast-feeding.[26] However, COCs have been reported to decrease milk quantity and quality.[26] Therefore, many providers suggest avoiding CHCs in women who are exclusively breast-feeding. If P.K. is planning to breast-feed, a progestin-only contraceptive is probably best and may be started 6 weeks postpartum to ensure the newborn is able to metabolize and clear the medication because progestins enter breast milk.

PROGESTIN-ONLY CONTRACEPTIVES

Progestin-Only Pill (Minipill)

CASE 47-3, QUESTION 3: What advantages and disadvantages of the minipill should you discuss with P.K.?

ADVANTAGES

The minipill is devoid of some of the nuisance side effects (Table 47-4) caused by estrogen (e.g., headaches, chloasma).[3] More importantly, estrogen-mediated hypertension and clotting factor changes will be avoided. Confusion with pill taking is minimized because there is no placebo week and all 28 pills in each pack are the same. Therefore, the missed-dose directions are the same whenever any pill is missed. Minipills also have noncontraceptive benefits, including decreased dysmenorrhea and bleeding and possible protection against pelvic inflammatory disease (PID) and endometrial cancer.[3] Women may also choose them because they are not estrogen containing and fertility returns rapidly after discontinuation.[3]

Theoretically, progestin use in the early postpartum period may decrease milk production because milk production is triggered by the decline in progesterone that occurs after delivery. However, no data have consistently shown this to be a problem in postpartum women.[26] Once breast-feeding has been established, progestins have not been shown to interfere with the quantity or quality of milk produced by a nursing mother. Thus, a contraceptive method that is nonhormonal or only contains progestin is preferred for a patient who plans to breast-feed her infant.

DISADVANTAGES

The minipill, with a failure rate of 0.3% to 8%, is similarly effective as COCs in preventing pregnancies (Table 47-1).[3] Minipills, however, must be taken even more regularly than COCs, and therefore, are not used often in women who are not breast-feeding (see Patient Instructions below). Some women on minipills ovulate regularly, and some shift back and forth between ovulatory and anovulatory (no ovulation occurring) menstrual cycles. Women who consistently have menses on the minipill may be ovulating

---

and should consider using a backup contraception or changing to a different method.

Irregular menses, decreased duration, and amount of menstrual flow, spotting, or amenorrhea commonly occur in women taking the minipill.[3] Because of this, patients often are concerned that they may be pregnant. Women who are exclusively breast-feeding will usually have amenorrhea. The high incidence of irregular menses associated with the minipill may mask underlying disease such as uterine fibroids or uterine cancer causing irregular bleeding. Other side effects reported with minipills include headaches, breast tenderness, mood changes, and nausea.

Minipills should be avoided if there is a personal history of breast cancer or unexplained vaginal bleeding. Caution should be exercised when using minipills in women with hepatic disease, multiple risk factors for cardiovascular diseases, ischemic heart disease, a current deep venous thrombosis or PE, or complicated diabetes (e.g., diabetes with nephropathy, neuropathy, retinopathy), or those taking medications that may interact with COCs such as hepatic inducers, St. John's-wort, and Bosentan (Table 47-5).[101,102]

PATIENT INSTRUCTIONS FOR THE PROGESTIN-ONLY PILL

CASE 47-3, QUESTION 4: What instructions should P.K. receive regarding the use of a minipill?

P.K. may begin taking the minipill on the first day of her menses.[3] Because she is breast-feeding and recently postpartum, she is less likely to have a menses. She could begin taking minipills immediately postpartum if she were not breast-feeding.

Because she is breast-feeding, it is recommended that she has to wait until 3 weeks postpartum if partially breast-feeding and 6 weeks postpartum to begin minipills if solely breast-feeding. If at 6 weeks postpartum, P.K. started her minipills on the first day of her menses, a backup contraception is not needed with the day 1 start. Alternatively, P.K. can use the quick start method, starting any day of her cycle and using a backup method for 48 hours.[3]

P.K. should be instructed to take the pill at the exact same time each day. If she is more than 3 hours late taking a pill, she should take the pill as soon as she remembers and should use backup contraception for 48 hours. This is quite different from the directions for COCs, so this point should be stressed with patients.

Injectable Medroxyprogesterone Acetate

Progestin-only contraceptives are available in two different injectable formulations of medroxyprogesterone acetate (MPA). Depo-Provera is given as a 150-mg intramuscular injection in the deltoid or gluteus maximus every 11 to 13 weeks.[3,103] More recently, depo-subQ provera 104 was approved. This product also contains MPA; however, it is given subcutaneously as a 104-mg dose every 12 to 14 weeks.[104] Injectable MPA inhibits ovulation, thickens the cervical mucus, and suppresses endometrial growth, making it a very effective contraceptive. Package inserts instruct the patient to begin the injectable MPA methods in the first 5 days of her menses and then no backup is required; however, P.K. may also begin any other time and use backup for 1 week.[3,103]

CASE 47-3, QUESTION 5: P.K. is now lactating and returns to the gynecology clinic for her second IM injection of MPA. She was given her first injection 3 months ago, immediately postpartum. She is experiencing prolonged intermenstrual bleeding and a 3- to 5-pound weight gain. Is this to be expected? What are the advantages and disadvantages of injectable MPA? How are the side effects managed?

ADVANTAGES

Injectable MPA is a reasonable contraceptive choice for P.K. because she is breast-feeding and indicated she needed a long-term contraceptive. Among its benefits are a low failure rate of 0.3% to 3% (Table 47-1), ease of use, lack of estrogenic side effects, decreased dysmenorrhea and monthly blood loss, and a reduced risk of endometrial cancer.[3,26] Other noncontraceptive benefits may include a reduction in seizure frequency in epileptic patients and a possible reduction in ovarian cancer.[3,26] Furthermore, contraceptive efficacy is not reduced by the concurrent use of anticonvulsants or certain antibacterials as is seen with COCs.[6,7] Depo-subQ provera 104 is also indicated for pain caused by endometriosis.[104]

DISADVANTAGES

Patients with breast cancer should not use injectable MPA owing to concerns that breast cancers are hormonally sensitive and the prognosis may worsen for some women.[6,7] Injectable MPA should be used with caution in women with unexplained vaginal bleeding (MPA may cause irregular bleeding and may mask conditions resulting in vaginal bleeding such as cervical or uterine cancer), multiple risk factors for cardiovascular diseases, ischemic heart disease or multiple risk factors for cerebrovascular disease, or a current VTE or PE (for medical eligibility, see https://www.cdc.gov/mmwr/volumes/65/rr/rr6503a1.htm?s_cid=rr6503a1_w).[7] Because clotting factors have not been shown to be clinically affected by injectable MPA, some experts disagree with the manufacturer's labeling for the injectable MPA products, which lists a history of prior thromboembolism as a contraindication.[5–7,103,104] Some clinicians also begin injectable MPA immediately postpartum rather than waiting 6 weeks postpartum, as directed by the package insert.[7]

Estrogen production declines in women using injectable MPA, so P.K. should be told that injectable MPA may decrease bone mineral density (BMD).[103] Loss of BMD may be of particular concern in adolescent patients. Numerous studies have found that women receiving injectable MPA have lower BMD compared with nonusers.[105] Although there have been reports of stress fractures in injectable MPA users, no studies to date have documented an increased rate of hip or vertebral fractures in injectable MPA users.[106] Also, BMD has been shown to recover after discontinuation of the injections.[4] The manufacturer of both products recommends that patients do not use injectable MPA longer than 2 years unless they are unwilling or unable to use other methods.[103]

P.K. must understand that injectable MPA frequently causes irregular bleeding or spotting during the first few months or more of use because estrogen is insufficient to maintain the endometrium. After 1 and 2 years of Depo Provera use, 55% and 68% of women experience amenorrhea, respectively.[103] With depo-subQ provera 104, 56.5% of patients experienced amenorrhea after 1 year.[104] In addition, during the postpartum period, irregular bleeding may occur as well. Although not harmful, amenorrhea leads to discontinuation of injectable MPA in 13% of patients.[103] All patients beginning injectable MPA should be informed that during the first year of use they might have menstrual changes. If unusually heavy or continuous bleeding occurs, P.K. should be evaluated. P.K. should be counseled and reassured that her intermenstrual bleeding probably will resolve in the next few months. If the bleeding is bothersome, a 4- to 21-day course of oral estrogen (e.g., conjugated estrogen 0.625–2.5 mg/day) or a COC with 20 mcg of EE will minimize or eliminate the bleeding.[8] However, the bleeding may recur after discontinuation of the estrogen. Low-dose estrogen may be continued if bleeding recurs.

Weight gain is another concern with injectable MPA. The mean weight gain after 1 year of therapy with injectable MPA was about 5 lb in two-thirds of users.[103] Depo-Provera users typically gain a total of about 8 lb in 2 years, nearly 14 lb in 4 years, and 16.5 lb in

6 years. Depo-subQ provera users gain a little less weight, 3.5 lb in the first year of use, and 7.5 lb after 2 years.[104] Other side effects include mood changes, hair loss, and headaches. P.K. should be counseled on the weight gain associated with injectable MPA. P.K. has already reported an increase in weight since she gave birth 3 months ago, which may be caused by injectable MPA, or possibly her weight is fluctuating because of her recent delivery.

The long return to fertility time is another disadvantage of injectable MPA. After the last injection of 150 mg of MPA, conception was delayed approximately 10 months in half of users.[96] The remaining users took longer to become pregnant, with nearly all users becoming pregnant by 18 months. There are less data on return of fertility with the 104-mg dose of MPA. A small study showed that the median time to ovulation was 10 months, with most women ovulating within 1 year of their last injection.[104] Because P.K. is 35 years old, she should be counseled on the return to fertility time with injectable MPA use in case she desired to have children in the near future. She has indicated that she is not interested in having any more children; however, the long return to fertility time with injectable MPA should be explained to all women, especially those older than 35 years of age.

Subdermal Implant

CASE 47-3, QUESTION 6: P.K. returns to the clinic 7 months postpartum for her third MPA injection. She started menstruating today after missing two appointments; she is now 1 month late for her MPA dose. She states her busy family life and work schedule make it difficult to attend appointments. She also does not like the weight gain and prolonged intermenstrual bleeding that has occurred during the past few months. She read that an implant is available and she would like to know whether this might be a better option for her. What information should you give P.K.?

The contraceptive implant (Nexplanon) contains 68 mg of etonogestrel in a single, thin, radiopaque, rod.[107] The rod is inserted subdermally in the upper inner arm using a needle and a local anesthetic. Once inserted, the implant is effective for up to 3 years. Nexplanon should be inserted during the first 5 days of menses, and no backup contraception is required. A small incision is required to remove the implant. The etonogestrel implant has the same mechanism of action as injectable MPA. The product was first marketed as Implanon; however, Implanon was not radiopaque and at times difficult to locate for removal. The radiopaque property of Nexplanon is preferred for ease of removal; therefore, Implanon is no longer manufactured.

ADVANTAGES

The contraceptive implant is a relatively new product, so information on its protection against cancers or effects on other diseases such as cardiovascular disease is limited. Women using the implant reported amenorrhea, decreased menstrual cramping, and less anemia than nonusers.[3] Also, decreases in BMD have not been shown with this product. Fertility returns quickly after the removal of the implant, and this will be a benefit to P.K. if she decides to have another child, given her age.

DISADVANTAGES

As with the injectables, irregular bleeding is likely and is the most common cause of discontinuation. Side effects reported with the implant are headaches, mood changes, and acne. Nexplanon is not recommended for patients on medications that induce hepatic enzymes (e.g., anticonvulsants) as they may decrease contraceptive efficacy. Weight gain is also common, with users gaining 2.8 lb after 1 year and 3.7 lb after 2 years.[108] So P.K. may still experience weight gain with this product. The implant is not recommended for patients with a current VTE; however, it may be used in patients with a personal or family history of VTE.[6,7]

INTRAUTERINE DEVICE AND INTRAUTERINE SYSTEM

CASE 47-3, QUESTION 7: P.K. is concerned about weight gain and is not interested in a subdermal implant. What other long-term, reversible contraceptive methods might work for her? Is P.K. a candidate for an intrauterine device (IUD) or intrauterine system (IUS), and if so, what information would you provide her?

Background and Mechanism of Action

Despite concerns (increased risk of PID, tubal scarring, and infertility) with early IUDs, also known as intrauterine contraceptives (IUCs), the current devices offer a safe and effective method of contraception.[110] Currently, there are four products on the market that include the ParaGard T 380A (copper) IUD, Mirena, Skyla, Kyleena, and Liletta (levonorgestrel) IUSs. Although the IUDs and IUSs available today are a safe and effective method of contraception, they are still not as popular in the United States (1%–6% of women are users) as they are worldwide (12% of married women of reproductive age are users).[110–112]

The copper IUD has a polyethylene body that is wound with copper wire. Once inserted, the copper IUD may be left in place for 10 years.[113] The Mirena, Skyla, Kyleena, and Liletta IUSs also have polyethylene bodies, with levonorgestrel reservoirs in the vertical stem of the T that provide levonorgestrel daily. Mirena and Kyleena are effective for 5 years and provide 20 mcg and 17.5 mcg of levonorgestrel daily, respectively.[114,115] Skyla is slightly smaller in size and provides 14 mcg of levonorgestrel daily after 24 days and is effective for up to 3 years.[116] Similarly, Liletta is effective for 3 years and provides levonorgestrel 18.6 mcg daily, decreasing to 16.3 mcg at 1 year, 14.3 mcg at 2 years, and 12.6 mcg at 3 years.[117]

Failure rate of the copper IUD is 0.6% to 0.8% for the first year compared with 0.2% for the levonorgestrel IUS (Table 47-1). Both IUDs and IUSs are inserted by a healthcare provider in the office. The procedure usually takes only a few minutes and does not require sedation. Many providers will recommend that patients take a dose of an NSAID before the insertion visit.

Possible mechanisms of action for copper IUDs include prevention of fertilization and implantation and the copper interfering with sperm transport, viability, or number.[113] The levonorgestrel IUS is believed to work by thickening the cervical mucus, preventing sperm from entering the uterus, altering the endometrial lining, preventing ovulation, and altering sperm activity.[113]

Advantages

Both the copper IUD and the levonorgestrel IUS are very effective, reversible, long-term methods that are easy to comply with.[3] The copper IUD is a particularly beneficial option for women who desire a nonhormonal method of contraception. The levonorgestrel IUS has the advantages of reducing menstrual bleeding and cramping as a result of the progestin.

Although the initial cost of inserting an IUD or IUS is high (around $500 for the device plus insertion costs), there are no ongoing monthly costs to P.K. as there are with other methods. Therefore, the IUD or IUS becomes more cost-effective when used for more than 1 year.

Disadvantages

Menstrual changes are the most common side effect of IUDs and IUSs.[3] Copper IUD users are more likely to have heavier menstrual bleeding and cramping. Levonorgestrel users should expect to have irregular bleeding and spotting during the first 3 months after insertion. After 3 months, however, levonorgestrel IUS users report lighter menses and reduced cramping.

Both IUDs and IUSs are contraindicated in women with certain anatomic abnormalities of the uterus (e.g., distortion of the uterus, cervical stenosis, or cervical lacerations), unexplained vaginal bleeding, cervical cancer, and PID or other active genital infections. They should be used with caution in women who are HIV-positive or are immunosuppressed (for medical eligibility, see https://www.cdc.gov/mmwr/volumes/65/rr/rr6503a1.htm?s_cid=rr6503a1_w).[7]

The levonorgestrel IUSs should be used with caution in women with a current VTE or PE. Although the serum levels of levonorgestrel are low, the manufacturers currently do not recommend that women with active or past breast cancer use the device.

Both IUDs and IUSs are preferred for women in monogamous relationships or who are able to have strict use of condoms as IUD users are more likely to experience PID than nonusers. For all patients, the greatest risk of PID occurs shortly after insertion.[118] To prevent this from occurring, all patients should be tested for gonorrhea and chlamydia before IUD or IUS insertion and evaluated for risk factors of contracting STIs (e.g., multiple partners, unprotected intercourse). Women who are positive for an STI should consider an alternative form of contraception until the infection has resolved. Alternatively, once treatment is provided, an IUD or IUS may be initiated and the woman counseled on ways to prevent STIs.[6,7]

If an IUD or IUS user becomes pregnant, the likelihood that the pregnancy is ectopic is higher (i.e., the ratio of ectopic to uterine pregnancies is higher in IUD or IUS users).[113,114] Common complaints of IUD use include excessive uterine bleeding, spotting, or pain. The device may be removed as a result of these issues. Spontaneous expulsion of the IUD occurs in about 2% to 6% of women within the first year.[3] Rarely, an IUD or IUS may become embedded in the endometrium or partially or totally perforate the uterine wall. P.K. should be instructed to look for the warning signs of a possible complication with IUD or IUS use, such as abdominal pain or abnormal vaginal discharge.

OTHER NONHORMONAL CONTRACEPTION

CASE 47-4

QUESTION 1: C.J. is a 22-year-old HIV+ woman presenting to the clinic for routine checkup and depot medroxyprogesterone acetate injection. She is currently using depot medroxyprogesterone acetate IM injection every 12 weeks and taking Atripla (efavirenz 600 mg/tenofovir 300 mg/emtricitabine 200 mg) 1 tablet by mouth daily.

Vitals today: height, 5′6″; weight, 116 lb
Blood pressure, 124/81 mm Hg
Heart rate, 89 beats/minute
Respiratory rate, 12 breaths/minute
Temperature, 96.8°F
Laboratory test results: CD4, 581
HIV-1 RNA, <75 copies/mL (undetectable)

C.J. wants to make sure she does not get pregnant and is recommended to use a barrier method in addition to depot medroxyprogesterone acetate. C.J. mentions that she is concerned about STIs and more specifically transmission of HIV. What barrier methods are available, and which one is best to recommend for C.J.?

Diaphragm and Cervical Cap

The diaphragm is a soft latex or silicone rubber cap with a metal spring reinforcing the rim.[3] The device is inserted vaginally and placed over the cervical os to mechanically block access of sperm to the cervix. The diaphragm is held in place by the spring tension of the rim, vaginal muscle tone, and the pubic bone.

A cervical cap marketed as FemCap is made of silicone.[119] The FemCap is kept in place by suction formed between the cervix and the device. Because all of these devices do not fit tightly enough to be a complete barrier to sperm, spermicidal gel must be applied to each device before it is inserted.

The first-year failure rate with diaphragms is 6% to 16% (Table 47-1).[3] C.J. should be counseled that diaphragms are less effective than other available methods. Because breast-feeding offers some protection against pregnancy, breast-feeding women may be the best candidates for the diaphragm. Failure rates of cervical caps range from 9% to 16% in nulliparous women and 20% to 32% in parous women (Table 47-1).[3] Studies of an earlier version of the FemCap found a failure rate of about 14% and about 8% for the second-generation FemCap.[119]

TYPES AND FITTING

Diaphragms must be properly fitted to be effective. They are available in different sizes (50–95 mm in diameter) and different styles of construction of the circular rim. The goal of fitting a diaphragm is to select the largest rim size that is comfortable for the patient.[3] A diaphragm that is too small may become dislodged during intercourse because vaginal depth increases during sexual arousal. Conversely, a diaphragm that is too large may cause vaginal pressure, abdominal pain or cramping, vaginal ulceration, or recurrent urinary tract infections. Proper size is estimated during bimanual examination, and several diaphragm sizes may need to be tried by the healthcare provider to find the right size for the patient. If C.J. gains or losses 10 to 20 lb, has a pregnancy, or has abdominal or pelvic surgery, the diaphragm would need to be refitted.

The FemCap is shaped like a sailor's hat[119] (see http://www.femcap.com/). It is available in three sizes, and size selection depends on the patient's pregnancy history; the 22-mm FemCap is for patients who have never been pregnant, the 26-mm one is for women who have miscarried or had a cesarean section, and the 30 mm size is for women who have vaginally delivered a full-term baby.

C.J. would likely be able to tolerate the diaphragm or FemCap. Fitting will depend on the device that she selects. These barrier methods, however, do not protect against STIs, which is important to C.J. when selecting her barrier method, and therefore, are not the best choice.

PATIENT INSTRUCTIONS, ADVANTAGES, AND DISADVANTAGES

The diaphragm and FemCap offer pregnancy prevention without the use of hormones, and women only need to use the devices when they are sexually active.[3,119] All of these devices are available only by prescription, should not be used during menstruation, may be difficult to insert and remove for some patients, and are not as effective as the hormonal methods or IUD. All devices should be inspected for holes or puckering (small areas of wrinkle) before use.

The diaphragm should not remain in the vagina for more than 24 hours.[5] Toxic shock syndrome (TSS) has been associated with diaphragm use, and women should be alert to its symptoms, which include fever, diarrhea, vomiting, muscle aches, and a sunburn-like rash. Allergic reactions to the latex or spermicides also have been reported.

The diaphragm should always be inserted before intercourse; it can be inserted as long as 6 hours before intercourse if desired.[3] The diaphragm should not be removed for at least 6 hours after intercourse. One teaspoon of spermicidal gel should be placed into the dome of the diaphragm before insertion. If intercourse is repeated, a new application of spermicide should be inserted vaginally without removal of the diaphragm.

To use the FemCap, first apply about one-fourth teaspoon of spermicide inside the bowl and one-half teaspoon on the other side that will face the vagina (between the brim and the dome).[119] Insert the FemCap with the long brim side first and the dome side up. Push until the cap is in contact with the cervix. More spermicide should be applied if intercourse is repeated. The FemCap should be inserted at least 15 minutes before sexual arousal and can be left in for up to 48 hours. The FemCap must be left in place for a minimum of 6 hours after intercourse.

Both devices should be washed with mild soap and water, rinsed and dried, and stored in the accompanying container. Oil-based products also may decompose the latex of the diaphragm and should not be used. These devices should be replaced every year or sooner if there are signs of wear or holes.

Vaginal Sponge

The vaginal sponge is another barrier method. It was taken off the market in 1995 and re-released in 2003. The sponge contains a polyurethane foam and 1 g of nonoxynol-9 (spermicide). The sponge is inserted into the vagina and placed against the cervix. It may be worn up to 24 hours. After intercourse, the sponge should remain in place for 6 hours. The sponge works in three ways: It acts as a spermicide, is a mechanical barrier, and absorbs semen. The failure rate reported is 18% for nulliparous women and 36% for parous women (Table 47-1).[3] Irritation or ulceration of the cervix and vaginal mucosa may occur. If the sponge is not removed within 24 hours or if particles remain after removal, toxic shock syndrome could be an issue. Because the sponge may cause irritation and does not provide protection against STIs, it may not be best for C.J.

Male Condoms

Male condoms are an effective method of contraception when used properly. The failure rate with condoms is 2% to 18% (Table 47-1).[3] Many different brands of condoms are available in the United States. The brands differ in size, shape, color, material, and the presence or absence of lubricants or spermicide. The chief noncontraceptive benefit of latex condoms is the prevention of STIs (including gonorrhea, chlamydia, and HIV), and they can be used for vaginal, anal, or oral sex.[6] Condoms are readily available without a prescription and do not cause systemic side effects such as the hormonal methods. However, some complain that condoms reduce sensitivity and spontaneity. The most commonly used and least expensive male condom is made of latex.[3] Male condoms made of polyurethane and lambskin are recommended for men or women allergic to latex. Polyurethane condoms are more expensive and sometimes break more easily than latex condoms, but they also conduct heat better than latex.[120] Lambskin condoms also conduct heat well but do not offer the same protection against STIs as latex and polyurethane. Lambskin condoms are not recommended for those who are concerned about STIs.[120]

Because the pre-ejaculatory secretions may contain sperm, the male condom should be applied before vaginal contact.[3] When using a male condom, the man or his partner should hold the tip of the condom and unroll it down to the base of the erect penis.[6,120] Most practitioners recommend lubricated condoms with resevoir ends to prevent breakage and collect the ejaculate. Oil-based lubricants can degrade male latex condoms and should be avoided. Oil-based lubricants, however, may be used with polyurethane or lambskin condoms. Condoms should be used only once by their expiration date and stored in a cool, dry place, away from prolonged periods of heat or light.

Latex condoms would be best for C.J. and her partner to prevent the transmission of STIs.

Female Condoms

The female condom is less effective, with a 21% failure rate (Table 47-1).[3] The original female condom known as the FC1 is made of polyurethane. Recently, the second-generation female condom (FC2) has become available replacing the FC1 (see http://www.fc2.us.com/).[121] The FC2 is made of a nitrale sheath or pouch and polyurethane ring at the closed end of the pouch. Both condoms consist of a smaller, circular, inner ring (which secures the device around the cervix like a diaphragm) and a larger ring around the opening of the condom.

The inner ring should be compressed and inserted vaginally as far as it will go, and the larger ring remains outside of the vagina, protecting the external genitalia. Female condoms should also be inserted before sexual contact; they may be inserted up to 8 hours before intercourse. The FC2 contains a silicone-based lubricant inside of the condom but additional lubricant may be used. Oil-based or water-based lubricants can be used with both female condoms. Just like male condoms, they should be used by their expiration date, not reused, and stored in a cool, dry place, away from heat or light.

Disadvantages of female condoms include cost (about $3 each), squeaking noise during use, and insertion difficulty.[3] Condoms may also break, although this is less likely with the female condom. Male and female condoms should not be used together as this may increase the risk of breakage.

An advantage for C.J. to use the female condom is that she has control of her own protection and does not need to rely on her partner to make sure they are both protected. The female condom is a good alternative for C.J.

Vaginal Spermicides

CASE 47-4, QUESTION 2: C.J. would like to use a spermicide along with condoms. What options does she have and how effective are spermicides when used alone? What dosage form should C.J. use? How should she be instructed to use a vaginal spermicide? What side effects can be anticipated?

Vaginal spermicides currently are available as gels (jellies), suppositories, foams, and films.[3,120] Most of these products use a nonionic surfactant, nonoxynol-9, as the spermicide. First-year failure rates with these dosage forms range from 18% to 29% (Table 47-1).

Table 47-6 compares the different spermicidal products.[3,120] The different characteristics of the products can help guide C.J. when selecting a dosage form. Regardless of the dosage form, a new dose of spermicide should be applied before each act of intercourse.

Spermicides may cause genital irritation and in some patients lead to ulceration. Likely for this reason, spermicides have been shown to increase the transmission of STIs, including HIV, gonorrhea, and chlamydia. Spermicides may not be the best choice for C.J. and her partner to prevent the risk of STI transmission.

Table 47-6

Comparison of Vaginal Spermicides[120]

Formulation	Brand Name Examples	How to Use	Onset of Action	Duration of Action
Gel	Conceptrol, Gynol II	Fill applicator, insert applicator vaginally as far as it will comfortably go, press plunger of applicator to deposit spermicide near the cervix.	Immediate	1 hour
Film	VCF	Fold film in half, fold over finger, use finger to insert as far as it will comfortably go.	15 minutes	3 hours
Foam	VCF	Shake foam canister, fill applicator, insert applicator vaginally as far as it will comfortably go, press plunger of applicator to deposit spermicide near the cervix.	Immediate	1 hour
Suppository	Encare	Unwrap, use finger to insert as far as it will comfortably go.	15 minutes	1 hour

EMERGENCY CONTRACEPTION

CASE 47-4, QUESTION 3: C.J. presents to a pharmacy 4 months later and says she missed her MPA injection last month. She had intercourse 4 nights ago with a condom and is worried she might become pregnant. She wants to know whether she should use the "morning-after pill." What do you tell C.J. about emergency contraception options? Is C.J. a candidate for emergency contraception?

Emergency contraception (EC), also referred to as the morning-after pill, is postcoital contraception useful for women who did not use a contraceptive (e.g., forgot, were assaulted) or whose method failed (e.g., broken condom, missed pill). Emergency contraception is available in a few methods, which include oral pills or an IUD.

Emergency Contraception Pills

Emergency contraceptive pills (ECPs) are available in a variety of formulations known as progestin-only, Yuzpe, and selective progesterone receptor modulators.

Currently, the one dose progestin-only (levonorgestrel 1.5 mg) ECPs are available over-the-counter to all ages.[122] The one tablet should be taken within 72 hours of unprotected intercourse according the package labeling. Studies, however, have shown that progestin-only ECPs are still effective if taken up to 120 hours (5 days) after unprotected sex.[108,123] Progestin-only ECPs reduce the risk of pregnancy by a few potential mechanisms: preventing ovulation, preventing fertilization, or preventing implantation.[3] They reduce the average risk of pregnancy by 89% after a single act of intercourse when taken within 72 hours. ECPs are most effective when taken as soon as possible after intercourse; therefore, treatment should not be delayed. Progestin-only ECPs may not be as effective in women with a BMI of 26 or greater and should be recommended to use an alternative ECP but treatment should not be denied due to BMI.[122] The most common side effects with ECPs are nausea and vomiting.[3] C.J. should be instructed that if she vomits within 1 hour of taking ECPs, the dose should be repeated. C.J.'s menses may come early or late, but she should take a pregnancy test if her menses does not come within 3 weeks of taking ECPs. This may further be complicated if C.J. gets her next scheduled dose of injectable MPA.

As an alternative to progestin-only ECPs, regular COCs may be used as long as they contain levonorgestrel or norgestrel as the progestin. This is known as the Yuzpe method, which consists of high-dose progestin and high-dose estrogen. There are no marketed formulations of this method. Depending on the brand of COCs used, a differing number of pills are taken within 120 hours of unprotected intercourse as two separate doses 12 hours apart (see Table 47-1 footnote).[3] Compared with progestin-only ECPs, the Yuzpe method is associated with higher incidence of nausea and vomiting, and patients may wish to take an antiemetic before each dose.[108] Because progestin-only ECPs are widely available, easy to use, and more effective and have limited side effects, COCs are being used less often for EC.

A newer ECP classified as an oral selective progesterone receptor modulator (SPRM), ulipristal acetate (ella), was approved for use in the United States.[124] The 30-mg oral tablet should be taken within 120 hours of unprotected intercourse.[125] It is available by prescription only. Its mechanism of action is somewhat different from that of progestin-only ECPs. It has progesterone receptor antagonist and agonist effects; however, its main mechanism is through receptor antagonism at the uterus, cervix, hypothalamus, and ovaries, thus preventing ovulation even after the LH surge, which progestin-only ECPs may not do.[125] The only other SPRM on the market is mifepristone (RU-486), known for medical abortion use. Concerns were raised about the mechanism of ulipristal disrupting an existing pregnancy and leading to abortion. Current pregnancy exposure data do not suggest an increase in miscarriage. Ulipristal has not been shown to be as effective in women with a BMI of greater than 30 and may be ineffective in women with a BMI of 35 or greater but treatment should not be denied due to BMI.[122,124] It is recommended that those women use an alternative emergency contraceptive method.[122,124] Headache, dysmenorrhea, nausea, and abdominal pain were the most reported side effects in clinical trials.[124,125] If vomiting occurs within 3 hours of taking the dose, a repeat dose is recommended.[124]

In C.J.'s case, progestin-only ECPs are the better choice because she is taking medications that interact with COCs. She is within the window of 120 hours postcoitus making over-the-counter progestin-only ECPs an option. Ulipristal is another option and labeled for use 120 hours postcoitus, but would require a prescription and may delay C.J. from receiving timely emergency contraception.

Intrauterine Devices for Emergency Contraception

The copper-T IUD is also an effective method of emergency contraception when inserted within 5 days of unprotected sex.[3,108] There is no evidence that the progestin IUD is effective. An IUD

---

must be inserted by a healthcare provider and as such may not be used regularly for emergency contraception. The biggest advantage of using an IUD for emergency contraception is that it provides continued contraception for the patient. In addition, it is effective in women regardless of their BMI. Because C.J. is HIV-positive, an IUD may not be the best choice for her due to infection risk. Also, having to see a provider for an IUD is less convenient and makes ECPs the better choice for accessibility and timing.

MEDICAL ABORTION

CASE 47-4, QUESTION 4: C.J. presents to the clinic 4 weeks later stating that she missed her period and is concerned she may be pregnant. Her human chorionic gonadotropin test is positive, confirming pregnancy. C.J. considers terminating the pregnancy, stating she is not ready to have a child and is concerned about the antiretroviral medication effects on the baby. What options are there for medical abortion?

It is estimated that about one-half of pregnancies are unintended, so it is important for these women to have safe options.[2] C.J. should be counseled extensively about her options, including keeping the baby, adoption, and medical or surgical abortion. Compared with surgical abortion, medical abortion does not require a surgical procedure, so it is less likely to cause infection and is less costly.[3] Thus, some women feel more in control when choosing this option. However, some patients may not prefer medical abortion because it usually requires more medical visits and follow-up, has a slightly lower success rate (94%–97%; failures will need a surgical procedure), and involves more bleeding and cramping that usually lasts for 2 weeks.

There are many variations in how medical abortions are carried out, but the general treatment remains the same.[3] C.J. would first obtain baseline laboratory tests, including blood type and hemoglobin. She would be given either methotrexate, mifepristone, or both the same day to stop development of the pregnancy. In the United States, mifepristone, a progesterone receptor blocker, is more commonly used. Misoprostol is given to induce uterine contractions and expel the pregnancy.

Typically for a gestational age of 63 days or less, C.J. would be given mifepristone 200 mg orally on day 1, then misoprostol 800 mcg vaginally on day 2 or 3 (6–72 hours after the mifepristone dose).[3] Misoprostol may also be given as 400 or

600 mcg orally or buccally with higher doses of mifepristone (600 mg orally).[3,126–128]

If using methotrexate, 50 mg/m^2 is given IM on day 1 followed by misoprostol 800 mcg vaginally 3 to 7 days later.[3] Side effects may include nausea, vomiting, diarrhea, cramping, and vaginal bleeding (heavier than a menses). With either method, patients should follow up with their healthcare provider on about day 15 to make sure the abortion is complete. If complete miscarriage has not occurred, another method may be used, such as aspiration, to remove all pregnancy tissues.

Infertility

Erin C. Raney

CORE PRINCIPLES		CHAPTER CASES
1	Infertility is the inability to conceive after 12 months of unprotected intercourse. A major predictor of infertility is the age of the woman. Additional risk factors for both men and women include lifestyle factors, such as tobacco use and obesity, as well as primary and secondary causes of hypogonadism.	**Case 48-1 (Questions 1–3, 6), Case 48-2 (Questions 1, 2)**
2	The evaluation of infertility in women incorporates data from physical examination and laboratory assessments of pituitary and ovarian function. In men, the semen analysis and laboratory assessments of hormone levels provide key information related to gonadal function.	**Case 48-1 (Questions 3–6), Case 48-2 (Questions 1, 2),** **Figure 48-1** **Table 48-2**
3	Unexplained infertility is diagnosed after a thorough evaluation of both the man and woman reveals no identifiable cause. Treatment is empiric and often combines superovulation with intrauterine insemination or in vitro fertilization.	**Case 48-1 (Questions 7–10)**
4	Clomiphene citrate is a selective estrogen receptor modulator that is considered a first-line agent for superovulation in patients with unexplained fertility. Aromatase inhibitors are under investigation as alternative oral agents.	**Case 48-1 (Questions 8–10)**
5	In vitro fertilization is the most commonly used assisted reproductive technology, or procedure that involves manipulation of oocytes and sperm. Medications are used to stimulate multiple follicles for oocyte retrieval and to optimize implantation after embryo transfer.	**Case 48-2 (Questions 3–9),** **Table 48-4**
6	Controlled ovarian stimulation with gonadotropins is accomplished with follicle-stimulating hormone alone or in combination with luteinizing hormone. A gonadotropin-releasing hormone agonist or antagonist is administered to prevent interruption of the cycle by endogenous hormones. Human chorionic gonadotropin is injected in a single dose to finalize follicular development for oocyte retrieval.	**Case 48-2 (Questions 4–7),** **Tables 48-3, 48-5, 48-6, 48-7** **Figure 48-3**
7	A rare but serious complication of controlled ovarian stimulation is ovarian hyperstimulation syndrome. The risk is minimized by monitoring the development of follicles carefully with sequential transvaginal ultrasounds and serum estradiol levels.	**Case 48-2 (Questions 5, 7)**
8	Multiple gestation pregnancies are associated with maternal and neonatal	**Case 48-2 (Question 9)**

risks, including preterm birth and extended neonatal intensive care. These risks are considered when determining embryo transfer and cryopreservation plans.	
⑨ The diagnosis and treatment of infertility affects the couple emotionally, financially, and socially. Psychosocial support is an important aspect of care from the early phases of evaluation and diagnosis through all stages of treatment.	**Case 48-2 (Question 10), Table 48-8**

INTRODUCTION

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse.[1] The definition is based upon the observation that roughly 85% of couples with normal fertility will achieve pregnancy within 1 year.[2] Data from the 2006 to 2010 National Survey of Family Growth revealed that 6% of married women 15 to 44 years old, or 1.53 million, were infertile and approximately 12% of women in this age group had used infertility services.[3,4] Many factors affect infertility rates, but advancing maternal age appears to be a prominent influence. The incidence of infertility in women 15 to 24 years old was 7%, whereas in women 35 to 44 years old, it was 27%.[3] This is accompanied by an age-related increase in chromosomal abnormalities and spontaneous abortion rates.[5] The physiologic factors of reproductive aging are amplified by a trend toward delayed childbearing in the United States. In 1970, 1 out of 100 women had their first child at age 35 or older. In 2006, this increased to 1 out of 12 women.[6] Male fertility is impacted by age as well, with higher infertility rates after age 39.[3] However, determining the exact contribution of male age to infertility is complicated by the influence of female age.

The complex physical, psychological, and social implications have led to a national focus on infertility as a public health priority.[7] Treatment plans vary widely depending on the contributions of both female and male factors. An individualized approach is necessary to balance the risks and benefits of the various therapeutic options and maximize clinical outcomes.

PATHOPHYSIOLOGY AND DIAGNOSIS

CASE 48-1

QUESTION 1: T.R. is a 32-year-old woman who presents to her gynecologist with concerns that she and her husband, age 37, have not conceived despite having unprotected intercourse on average 2 to 3 times/week for the past 14 months. Her prior contraceptive method was a combined oral contraceptive which she used for 12 years and discontinued 2 years ago. At that time, the couple used male condoms until 14 months ago when they stopped using contraception altogether. What is the recommended initial approach to this couple's concern?

Evaluation of infertility generally begins after a couple has attempted to conceive for at least 12 months without success. Evaluation after just 6 months of unsuccessful conception is recommended in women older than age 35 or in those with a history of conditions associated with infertility, such as amenorrhea, endometriosis, or pelvic inflammatory disease.[2]

This couple has failed to conceive after 14 months of regular, unprotected intercourse, which supports an evaluation of both partners at this time. The diagnostic process first involves a thorough assessment of medical conditions, lifestyle parameters, and medication exposures. This is followed by complete physical examinations and laboratory assessments with other diagnostic procedures as warranted.

General Risk Factors

CASE 48-1, QUESTION 2: Additional information is obtained about the couple's social history. T.R. works as a bank teller and her husband is a financial planner. Neither T.R. nor her husband smoke tobacco or use illicit substances. Both drink one to two cups of caffeinated coffee each day and drink alcohol socially, an average of one to three drinks each on weekends. What lifestyle factors may contribute to infertility in this couple?

Lifestyle factors such as tobacco or illicit drug use and caffeine intake are known contributors to infertility. Tobacco use can be linked to 13% of female infertility cases.[8] In addition to the negative effects on fetal development during pregnancy, tobacco use can worsen ovulatory function. It also induces chromosomal changes that alter sperm production and function.[8] Caffeine is associated with decreased fertility with higher levels of intake, but moderate use of one to two cups of coffee or equivalent appears to have minimal impact. Although a link between alcohol use and infertility is not definitive, it is recommended that women limit their use to no more than one drink per day. Complete abstinence from alcohol is recommended once pregnancy is confirmed.[9] Use of illicit substances such as marijuana impairs fertility and decreases the success of fertility treatments.[9,10] Occupational and environmental exposures to pesticides, heavy metals, and toxins such as organic solvents used in dry cleaning and printing are additional contributors.[9]

The couple's lack of tobacco or illicit drug use eliminates these as potential contributors and their occupations do not fit known high-risk exposure profiles. Their pattern of caffeine and alcohol use is not greater than the amount currently documented to affect fertility. Assessment of other causes of infertility is warranted.

Female Factor Infertility

OVULATORY DYSFUNCTION

CASE 48-1, QUESTION 3: T.R.'s medical history is significant for exercise-induced asthma diagnosed at age 10. Her medications include an albuterol inhaler used as needed for shortness of breath. She is 5 feet 5 inches tall and weighs 140 lb. Her reproductive history reveals menarche at age 13, no prior pregnancies, and regular menstrual cycles approximately 25 to 26 days in length since discontinuing the oral contraceptive. She reports the menstrual bleeding phase to be 4 to 5 days in length and does not complain of excessive bleeding. A physical examination is performed along with a pelvic examination with no notable abnormalities. What information does this provide about possible female factors associated with infertility?

An important focus when evaluating causes of infertility is ovulatory function, which is associated with up to 40% of female factor infertility.[2] A thorough reproductive history should document age of menarche, menstrual cycle patterns, premenstrual symptoms, and previous pregnancies. A history of regular menstrual cycles of 21 to 35 days with premenstrual symptoms or dysmenorrhea is considered consistent with ovulatory cycles.[2]

Ovarian function is regulated through complex feedback mechanisms within the hypothalamic–pituitary–ovarian axis (see Chapter 50, Disorders Related to the Menstrual Cycle, Fig. 50-1). This involves release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary gland, and estrogen and progesterone from the ovaries. Table 48-1 provides an overview of abbreviations commonly associated with diagnosis and management of infertility for use throughout the chapter.

Conditions such as thyroid dysfunction, hyperprolactinemia, and polycystic ovary syndrome (PCOS) can disrupt these feedback mechanisms and induce anovulation. Signs may be evident upon physical examination, including an enlarged thyroid (thyroid dysfunction), abnormal discharge from the breast (hyperprolactinemia), or signs of hyperandrogenism (PCOS). Obesity is another feature associated with PCOS. Conversely, extremely low body weight and excessive exercise may negatively impact ovulatory function at the hypothalamic level. Weight gain improves menstrual regulation in women with anovulation associated with low body fat. Primary ovarian failure can result from exposure to chemotherapy agents or radiation treatments as well as ovarian surgery. As previously discussed, the aging process itself is characterized by diminished ovarian follicular reserve.[2]

Table 48-1

Common Abbreviations Associated with Infertility Diagnosis and Treatment

ART	Assisted reproductive technology
CC	Clomiphene citrate
COS	Controlled ovarian stimulation
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
hCG	Human chorionic gonadotropin
HSG	Hysterosalpingogram
hMG	Human menopausal gonadotropin
IUI	Intrauterine insemination
ICSI	Intracytoplasmic sperm injection
IVF	In vitro fertilization
LH	Luteinizing hormone
OHSS	Ovarian hyperstimulation syndrome
OI	Ovulation induction
SO	Superovulation

T.R.'s reproductive history is consistent with regular menstrual cycles which are likely ovulatory. It would be helpful to identify whether she reports any symptoms of premenstrual syndrome or dysmenorrhea which are associated with ovulatory cycles. Her physical examination is unremarkable and her medical history does not reveal any conditions associated with anovulation. Her weight is not likely a factor because her body mass index of approximately 23 kg/m^2 is in the normal range. She has no known history of exposure to chemotherapy or ovarian surgery which could directly impact ovarian function. The only parameter consistent with female factor infertility is T.R.'s age. At 32 years old, she may be experiencing an initial age-related decline in ovarian function consistent with infertility.

CASE 48-1, QUESTION 4: T.R. reports using a home ovulation test kit for the last two menstrual cycles which both yielded positive results. She is referred for a series of laboratory tests with the following findings:

Thyroid-stimulating hormone, 3.2 mIU/L
Prolactin, 8.4 ng/mL
Cycle day 3 FSH, 4 mIU/mL
Cycle day 3 estradiol, 38 pg/mL
What additional information about her ovulatory function can be determined from these results?

Several methods are available to further define ovulatory function. Basal body temperature monitoring is accomplished through the measurement of body temperature every morning upon waking with a basal or digital thermometer. Temperature fluctuations typically follow a biphasic pattern during the menstrual cycle, with a sustained rise in basal body temperature of approximately 0.5°F to 1.0°F after ovulation. If this pattern is apparent through daily documentation in a temperature diary, it can be assumed that ovulation occurred during that cycle. The accuracy of this method is complicated by daily temperature fluctuations, inconsistent measurement technique, and illness. It has largely been replaced by the use of home ovulation test kits that detect urinary LH. The patient initiates daily urine tests during the follicular phase, with the initial testing day determined by the length and regularity of her menstrual cycle (Fig. 48-1). A positive test documents the LH surge, signaling that ovulation will occur in an average of 24 hours.[2,11] Home ovulation test kits that detect changes in cervical mucus or saliva samples are not typically used for diagnostic purposes. They are useful, however, for patients who are timing intercourse during their most fertile period around ovulation.[9,11]

Indirect measurements of ovulation are available, but not widely performed. A serum progesterone concentration measured in the mid-luteal phase greater than 3 ng/mL is considered consistent with an ovulatory cycle. Alternatively, an endometrial biopsy performed just prior to menses measures the degree of progesterone-stimulated growth, signifying whether ovulation likely occurred. The invasive nature of this test limits its feasibility in most diagnostic evaluations.[2]

In patients who are anovulatory, additional laboratory assessments of thyroid function and prolactin levels document potential secondary causes. Anovulation associated with hyperprolactinemia is treated with oral dopamine agonists such as cabergoline.[12] Elevated testosterone levels may correspond with physical signs of hyperandrogenism and PCOS. The treatment of PCOS is discussed elsewhere (see Chapter 50, Disorders Related to the Menstrual Cycle).

Assessment of ovarian reserve may be performed in women older than age 35 to help guide fertility treatment choices. There are multiple methods that can be used. One involves the measurement of basal levels of serum FSH with or without estradiol on day 2, 3, or 4 of the menstrual cycle, with day 1 being the first day of menses. Because the number of ovarian follicles declines with age, pituitary release of FSH increases. Therefore, elevated levels of basal FSH (>10–20 IU/L) suggest diminished ovarian function. Unfortunately, the interpretation is complicated by individual variability in FSH levels from cycle to cycle as well as varying laboratory-specific reference ranges. A serum estradiol level of >60 to 80 pg/mL with normal FSH levels is also associated with a poor prognosis for success with infertility treatments.[2,13] Measurement of inhibin B, which is secreted from the ovarian granulosa cells during the follicular phase of the menstrual cycle, is an additional marker. Low levels of inhibin B correlate with elevated FSH levels and a possible decline in ovarian function. However, due to the variability with this measurement, it is not recommended as a routine evaluation of ovarian reserve.[13]

The clomiphene citrate challenge test provides another option for assessing ovarian reserve. This involves the administration of clomiphene citrate (CC), a selective estrogen receptor modulator, at a dose of 100 mg once daily on days 5 through 9 of the menstrual cycle. In addition to the estradiol and FSH measurements on day 3 as described previously, FSH is also measured on day 10. The expected response is suppression of FSH by the developing ovarian follicles. Elevated levels at either day 3 or 10 suggest diminished ovarian reserve. The value of this test as a predictor of response to ovarian stimulation is not clearly supported in the literature.[2,13]

Direct visualization of the ovaries through a transvaginal ultrasound may be used in conjunction with the hormone testing described previously. An assessment of ovarian volume and the antral follicle count can be made. The antral follicles, or those 2 to 10 mm in diameter, are responsive to FSH in the early follicular phase and decline in number with age. An antral follicle count of 3 to 6 is considered low and predicts poor ovarian response to various infertility treatments.[2,13]

The laboratory assessment of T.R. provides additional data regarding her ovarian function. Ovulatory cycles are supported by the positive urinary LH surge with the home test kit as well as the normal (nonelevated) day 3 FSH and estradiol levels. Her normal thyroid-stimulating hormone and prolactin levels indicate a low probability of secondary causes of anovulation. Because T.R. is younger than 35 and there are no other indicators of ovulatory dysfunction, additional testing of ovarian reserve may not be necessary. The initial findings of T.R.'s infertility assessment show that ovulatory dysfunction is not likely to be a contributor.

STRUCTURAL FACTORS

CASE 48-1, QUESTION 5: Because T.R. has normal ovulatory function, further causes of female factor infertility will be investigated. What testing is recommended to rule out structural causes of infertility?

Structural abnormalities in the uterine cavity or fallopian tubes are additional causes of female factor infertility. These may develop in utero or result from scar tissue or lesions secondary to conditions such as endometriosis. In some cases of endometriosis, surgical interventions improve fertility outcomes, but this is highly dependent on the severity and location of the lesions.[14] Further discussion of the diagnosis and treatment of endometriosis is provided elsewhere (see Chapter 50, Disorders Related to the Menstrual Cycle). Pelvic inflammatory disease from sexually transmitted infections such as chlamydia or gonorrhea is a risk factor for tubal infertility.[2]

The use of invasive procedures to explore structural causes of female infertility is dictated by the reproductive history and findings of the physical examination and laboratory tests. Abnormalities of the ovaries, uterus, and fallopian tubes are evaluated through various procedures. Transvaginal ultrasonography utilizes vaginal insertion of an ultrasound probe to visualize ovarian structure and developing follicles. A hysterosalpingogram (HSG) is performed to confirm normal fallopian tube structure. During this process, dye is injected into the uterus through a catheter and visualized on X-ray to determine any blockages or malformations. Hysteroscopy and laparoscopy are more invasive procedures that allow for direct visualization of the uterus or pelvic anatomy. These are typically reserved for further examination of abnormalities detected by initial testing.[2]

Impaired cervical mucus production and quality are additional structural factors that can impact sperm motility and the fertilization process. Cervical mucus increases in volume and becomes thinner as the follicular phase progresses to facilitate sperm transport at ovulation. The “postcoital test” or microscopic examination of cervical mucus within hours of intercourse can be performed to confirm the presence of motile sperm, but is no longer recommended for routine use.[2]

In the evaluation of this couple, it is important to verify T.R.’s sexual history and any possible exposures to sexually transmitted infections, such as chlamydia. An HSG should be ordered to determine whether she has patent fallopian tubes and to provide basic information about the shape of her uterine cavity. If there are abnormal findings from this test, further hysteroscopic or laparoscopic procedures can be performed. A laparoscopy would be necessary to fully evaluate any peritoneal adhesions from undetected endometriosis, but her medical history does not warrant this invasive procedure at this time.

Male Factor Infertility

CASE 48-1, QUESTION 6: The results of the HSG are normal, so the infertility assessment turns now to the evaluation of T.R.’s husband. He is healthy with no chronic medical conditions or medication use. He denies symptoms of low libido or signs of erectile or ejaculatory dysfunction during intercourse. A complete physical examination, including the genitalia, reveals normal findings. His semen analysis yields the following results:

Semen volume, 5 mL
Sperm number, 400×10^6
Sperm concentration, 112×10^6/mL
Sperm total motility, 65%
Sperm progressive motility, 61%
Sperm vitality, 80%
Sperm morphology, 30%

A second semen analysis confirms these results. What conclusions about the cause of infertility can be made from these findings?

Infertility is associated with male factors in approximately 20% of cases. Male and female factors contribute to infertility in 30% to 40% of couples.[15] Male factor infertility is often an outcome of impaired sperm production or function, which can originate from a variety of causes. Impaired sperm production may be associated with hypogonadism resulting from testicular trauma, cryptorchidism, radiation, or antiandrogen medications.[15,16] Varicoceles, or dilated scrotal veins, affect testicular function in up to 40% of men with infertility. It appears that the resulting abnormal venous perfusion and elevated testicular temperature impair spermatogenesis.[17] Genetic conditions may disrupt androgen synthesis or cause defects in the LH or FSH receptor. Azoospermia, or no presence of sperm in the ejaculate, is also apparent in certain genetic disorders, such as Klinefelter syndrome. Pituitary tumors can reduce FSH and LH secretion and impair sperm production. Sperm transport defects result from erectile dysfunction, retrograde ejaculation, or obstruction of the vas deferens or epididymis. Medications such as antidepressants or antihypertensives can worsen libido and ejaculatory function.[16]

A complete physical examination of the man is performed to identify signs of androgen deficiency such as small testicular size or an abnormal pattern of male hair growth. In some cases, anatomic defects such as varicoceles can be identified and repaired surgically.[17] However, the primary evaluation tool for male infertility is the semen analysis. Although there are home test kits for male infertility that utilize a semen sample, they are not recommended for diagnostic purposes because a positive result merely confirms that the sperm count is above a predetermined level. There is no quantification of the number of sperm or evaluation of sperm quality, so it does not rule out sperm abnormalities. A detailed semen analysis is required to fully evaluate male factor infertility. The evaluation of two semen analyses on different occasions is recommended.[15] The World Health Organization publishes reference values for semen characteristics (Table 48-2).[18] Results lower than these cut-off values are not definitive for male factor infertility, but do suggest the need to confirm the findings with a second semen analysis.[15]

Table 48-2

Semen Analysis: Lower Reference Limits for Selected Parameters

Parameter	Lower Reference Limit
Semen volume (mL)	1.5
Total sperm number (10^6/ejaculate)	39
Sperm concentration (10^6/mL)	15
Total motility (progressive + nonprogressive, %)	40
Progressive motility (%)	32
Vitality (live spermatozoa, %)	58
Sperm morphology (normal forms, %)	4

Source: World Health Organization, Department of Reproductive Health and Research. WHO Laboratory Manual for the Examination and Processing of Human Semen. 5th ed. Geneva, Switzerland: World Health Organization Press; 2010:224.

Abnormal findings on the semen analysis may be suggestive of the underlying cause of infertility. Low semen volume suggests structural causes of ejaculatory dysfunction. Additional hormone testing, including FSH, testosterone, and prolactin levels, may be necessary to distinguish factors associated with a low sperm count or motility. Low FSH and testosterone are consistent with hypogonadotropic hypogonadism.[16] If hyperprolactinemia is evident, any secondary causes such as medications are investigated. Certain antipsychotics, antihypertensives, or antidepressants can increase prolactin levels and should be discontinued and replaced with agents that do not increase prolactin. If the underlying cause cannot be addressed, a dopamine agonist may restore testicular function and sperm production.[12]

T.R.'s husband's medical history does not support an identifiable cause of altered sperm production or function. He does not report any signs of sexual dysfunction or take medications that may negatively affect libido or erectile or ejaculatory function. All components of the semen analysis are above the lower limit defined by the World Health Organization. His normal physical examination and medical history also support a lack of identifiable male causes of infertility. In this case, the extensive testing of both T.R. and her husband has revealed no obvious contributor to infertility.

TREATMENT APPROACHES

CASE 48-1, QUESTION 7: The couple completes their evaluation and is diagnosed with unexplained infertility. What is the initial approach to treatment?

The diagnosis of unexplained infertility, or no identifiable cause after evaluation, accounts for up to 25% of cases.[19] The treatment approach is empiric but typically incorporates medications to stimulate ovulation, often in conjunction with intrauterine insemination or other infertility procedures, which are discussed later in the chapter.

Regardless of the treatment approach, all couples pursuing pregnancy are encouraged to avoid tobacco, alcohol, and illicit substances, and limit caffeine intake.[9] The female partner should take a daily supplement containing 400 to 800 mcg of folic acid to reduce the risk of neural tube defects once pregnancy occurs.[20] Any chronic medications must be evaluated for potential safety issues during pregnancy and discontinued or switched to a safer alternative. Patients are encouraged to achieve and maintain a normal weight.[9] Recommendations pertinent to T.R. include discontinuation of alcohol use, limited caffeine intake, and initiation of a daily multivitamin with 400 to 800 mcg of folic acid. T.R. should also confirm plans for monitoring her asthma symptoms during pregnancy. Albuterol use during pregnancy will be continued, but the frequency of use will be monitored carefully.[21]

Ovarian Stimulation

There are two general treatment approaches to ovarian stimulation: “ovulation induction” (OI) and “superovulation (SO).” The approach depends on a patient’s underlying ovulatory function. Ovulation induction is utilized in patients who are not ovulating to promote an ovulatory cycle. This method may be accompanied by timed natural intercourse or the use of insemination procedures to achieve pregnancy. Superovulation, or controlled ovarian stimulation (COS), incorporates many of the same medications, but is appropriate for women who are already having ovulatory cycles but are still experiencing infertility. Additionally, SO is appropriate for infertility procedures where the development of multiple ovarian follicles is desirable (Case 48-2). The general approach to medication use with both strategies is described subsequently.

Anovulatory women with adequate ovarian reserve and no other treatable cause are candidates for OI. This process is designed to mimic the hormonal patterns of the normal menstrual cycle. Follicle-stimulating hormone guides the initial recruitment and development of ovarian follicles early in the menstrual cycle. This is followed by development of a dominant follicle and increased estradiol levels. The elevated estrogen triggers the LH surge and the release of the ovum mid-cycle for fertilization (Fig. 48-1). The goal of OI is the development of a single dominant follicle.[22]

The choice of medications for OI is dictated by hypothalamic–pituitary–ovarian function. With adequate hypothalamic function, an oral regimen of CC, which exhibits estrogen agonist and antagonist activity, is often utilized first line. Clomiphene citrate inhibits estrogen binding in the hypothalamus to stimulate release of GnRH and pituitary gonadotropins and induce ovarian follicular development. Ovulation is successful in approximately 75% of patients using CC.[19] Oral aromatase inhibitors are not approved by the US Food and Drug Administration (FDA) for OI, but also increase release of GnRH and pituitary gonadotropins through an estrogen antagonist effect.[19]

If hypothalamic or pituitary dysfunction is detected or if oral regimens are not successful, injectable gonadotropins are administered. The most common gonadotropin regimens use FSH administered alone or in combination with LH, depending on whether the patient has hypogonadotropic or eugonadotropic hypogonadism (Table 48-3).[23] Injections are initiated at low daily doses until a dominant follicle has matured. Ovulation is then triggered with an injection of human chorionic gonadotropin (hCG) to simulate the LH surge that naturally occurs mid-cycle. This is timed with natural intercourse or other infertility procedures to achieve pregnancy.[24]

Table 48-3

Gonadotropins for Ovulation Induction/Superovulation

Ingredient	Product Name	Strength/Dosage Form	Route of Administration
hMG (menotropins)	Menopur	Powder for reconstitution: 75 IU FSH activity and 75 IU LH activity/vial	SC
Urinary FSH (urofollitropin)	Bravelle	Powder for reconstitution: 75 IU FSH activity/vial	IM or SC
Recombinant FSH (follitropin alfa)	Gonal-f multi-dose	Powder for reconstitution: 450 or 1,050 IU FSH activity/vial	SC
	Gonal-f RFF 75 IU	Powder for reconstitution: 75 IU FSH activity/vial	SC

	Gonal-f RFF Redіject	Solution: 300, 450, or 900 IU FSH/pen	SC
Recombinant FSH (follitropin beta)	Follistim AQ Vial	Solution: 75 IU FSH/0.5-mL vial	IM or SC
	Follistim AQ cartridge for Follistim Pen	Solution:300, 600, or 900 IU FSH/cartridge	SC
Urinary hCG	Chorionic gonadotropin (generic)	Powder for reconstitution: 10,000 IU LH activity/vial	IM
	Pregnyl	Powder for reconstitution: 10,000 IU LH activity/vial	IM
	Novarel	Powder for reconstitution: 10,000 IU LH activity/vial	IM
Recombinant chorionic gonadotropin alfa	Ovidrel	Prefilled syringe: 250-mcg r-hCG/0.5 mL	SC

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; IM, intramuscular; LH, luteinizing hormone; r-hCG, recombinant human chorionic gonadotropin; SC, subcutaneous.

Accessed June 14, 2017.

The oral and injectable medications used for OI are also incorporated into regimens for SO. They are administered in doses and schedules intended to develop multiple ovarian follicles, rather than one dominant follicle. This results in a greater number of oocytes available for fertilization. Because T.R. has ovulatory cycles, but has unexplained infertility, SO is the treatment approach considered most appropriate.

CASE 48-1, QUESTION 8: What medication regimen is recommended for T.R.’s unexplained infertility?

There are multiple methods for ovulation stimulation that utilize oral or injectable medications. Clomiphene citrate is the most common initial choice because of the convenience and low cost of an oral regimen and the widespread experience with its use.

CLOMIPHENE CITRATE

The competitive binding of CC to estrogen receptors in the hypothalamus stimulates release of GnRH. This promotes gonadotropin release from the anterior pituitary, leading to follicular development, increased estradiol production, and ovulation. As previously described, the mechanism of action of CC requires an intact hypothalamic–pituitary–ovarian axis.[25] The typical initial dosing regimen for CC is 50 mg once daily for 5 days starting between days 2 through 5 of the menstrual cycle. Ovulation usually occurs 5 to 12 days after the fifth dose is taken. If ovulation is documented but pregnancy does not occur, the same dose of CC is used in future cycles. If ovulation does not occur, then the dose is increased by 50 mg with each subsequent cycle. Although the product labeling does not recommend doses above 100 mg/day, CC doses as high as 250 mg have been described in the literature.[25]

Superovulation for unexplained infertility with CC is recommended in combination with intrauterine insemination (IUI), because this improves pregnancy and live birth rates over CC alone or no intervention.[25] Intrauterine insemination introduces a processed semen sample directly to the uterus via a catheter placed through the cervix. The procedure is timed with ovulation to maximize sperm exposure for fertilization. This is accomplished by using a urinary ovulation home test kit to identify the natural LH surge or injecting hCG to trigger ovulation and planning the IUI 24 to 36 hours later. Due to the nature of the procedure, patients with bilateral obstruction of the fallopian tubes are not candidates for IUI.[26]

T.R.'s evaluation shows no evidence of hypothalamic or pituitary dysfunction, so she is an appropriate candidate for CC. Once her next cycle begins, she should initiate a 5-day regimen of CC 50 mg once daily starting on the fifth day of menstrual bleeding, with plans for an IUI following documentation of ovulation.

CASE 48-1, QUESTION 9: T.R. begins a regimen of CC and experiences hot flashes and nausea, but chooses to complete the 5-day course. What is the likely cause of her symptoms?

Vasomotor symptoms are a common complaint during a short treatment course of CC, occurring in approximately 10% of users. Additional side effects include headache, breast tenderness, irritability, mood swings, and nausea. Although visual disturbances are reported in less than 2% of patients, symptoms such as blurred vision or light sensitivity should be reported and evaluated to prevent serious complications.[19,25] All medications for SO can result in multiple gestation pregnancies. Clomiphene citrate for unexplained infertility is associated with multiple gestation in approximately 3% to 7% of pregnancies, primarily resulting in twins.[25] Early concerns about increased rates of ovarian cancer in women exposed to more than 12 cycles of CC have been minimized based on recent data.[25]

In this case, T.R. is experiencing side effects commonly associated with CC. They are not treatment limiting, and she is not reporting a change in vision that would require further evaluation. She can safely proceed with treatment by monitoring for an LH surge using a home ovulation test kit and undergoing IUI.

CASE 48-1, QUESTION 10: The pregnancy test after the first cycle of CC and IUI is negative. What other options are available for this couple?

Multiple treatment cycles with the combination of CC and IUI are commonly pursued, but there is little evidence for effectiveness beyond six attempts.[25] In some cases, alternatives to CC for SO may be desirable because of poor tolerability or treatment failure. Aromatase inhibitors or gonadotropins are suitable alternatives to combine with IUI.

AROMATASE INHIBITORS

The aromatase inhibitors letrozole and anastrozole are oral alternatives to CC, although they are not FDA-labeled for OI or SO. Aromatase is an enzyme that converts androstenedione to estrone and testosterone to estradiol. Aromatase inhibitors reduce systemic estrogen levels by blocking this conversion in the ovary, resulting in increased gonadotropin secretion and follicular development. The higher concentration of androgens that remains in the ovary increases follicular sensitivity to FSH and further facilitates development.[27]

The recommended administration schedule is similar to clomiphene: once daily for 5 days beginning on cycle days 3 to 5. Although daily doses of letrozole 2.5 or 5 mg or anastrozole 1 mg have been studied for this purpose, there is more evidence available for letrozole. Pregnancy rates with letrozole appear to be similar to that of CC.[28] Adverse effects experienced with aromatase inhibitors resemble those of CC and include vasomotor symptoms, nausea, and fatigue. The aromatase inhibitors do not affect cervical mucus or endometrial development, but this finding has not translated into improved pregnancy outcomes in clinical studies. Development of fewer follicles may result in a lower risk of multiple gestation pregnancy compared with CC. Initial concerns of the teratogenic potential of aromatase inhibition during fetal development prompted a warning against use in premenopausal women who are or may become pregnant.[27] However, surveillance studies do not demonstrate higher rates of congenital malformations with letrozole as compared to CC.[27,29] The early timing of administration in the cycle reduces the risk of fetal exposure. Continued monitoring of pregnancy outcomes is needed to confirm safety.

GONADOTROPINS

If oral agents are unsuccessful, SO can be attempted with injectable gonadotropins including FSH alone or in combination with LH (Table 48-3).[23] A standard protocol involves daily injections of FSH or a combination of FSH and LH to stimulate follicular development. Human chorionic gonadotropin is commonly administered as a single injection to finalize follicular development and induce ovulation.[19] Dosing recommendations, key differences between formulations, and risks associated with gonadotropin use are reviewed in more detail in Case 48-2.

T.R.'s complaints of vasomotor symptoms are well documented with CC. Although the aromatase inhibitors are another oral option, the likelihood of hot flashes is similar. However, if the couple continues to be unsuccessful with future cycles of CC plus IUI, letrozole can serve as an alternative prior to use of injectable gonadotropins. In vitro fertilization (IVF) is commonly reserved until after multiple

IUI procedures are attempted and unsuccessful.

Table 48-4

Description of Select Infertility Procedures

Classification	Procedure	Description
Insemination	Intrauterine, intracervical, intravaginal	Delivery of a prepared semen sample to the intended site (vagina, cervix, uterus) during ovulation
Assisted reproductive technology	Assisted hatching	Mechanical or chemical separation of the blastocyst from the zona pellucida (membrane surrounding the oocyte) during embryonic development in vitro
	Embryo cryopreservation	Freezing and storage of embryos for future ART cycles
	Gamete intrafallopian transfer	Laparoscopic transfer of the unfertilized oocytes and sperm to the fallopian tube for fertilization
	In vitro fertilization—embryo transfer	Transfer of one or more embryos resulting from in vitro fertilization into the uterus through the cervix
	Intracytoplasmic sperm injection	In vitro injection of the sperm into the oocyte
	Preimplantation genetic diagnosis/screening	Examination of oocytes, zygotes, or embryos for specific genetic conditions (diagnosis) or for general genetic alterations (screening)
	Zygote intrafallopian transfer	Laparoscopic transfer of the fertilized oocyte (zygote) into the fallopian tube

ART, assisted reproductive technology.

Assisted Reproductive Technology

OVERVIEW AND INDICATIONS

There are a variety of procedures to address infertility factors specific to each couple. Insemination processes (intrauterine, intracervical, and intravaginal) are categorized separately from those using assisted reproductive technology (ART), or the manipulation of oocytes and embryos (Table 48-4).[30] The Centers for Disease Control and Prevention monitors ART in the United States through the National ART Surveillance System. The use of ART is trending upward, with the number of cycles increasing from just over 122,000 in 2003 to more than 157,000 in 2012.[31]

The primary ART is IVF, which involves retrieval of oocytes after SO, fertilization in vitro, and transfer of the embryo(s) directly to the uterus through the cervix, bypassing the fallopian tubes (Fig. 48-2; Table 48-4).[31] Intracytoplasmic sperm injection (ICSI), or the injection of sperm directly into the oocyte during the fertilization process, accompanies IVF if severe sperm dysfunction is evident. A variety of ancillary procedures can be used based upon each couple's history and clinical presentation. These include genetic screening and cryopreservation of embryos. Assisted reproductive technology also allows couples to use donor sperm and/or oocytes to overcome severe sperm or ovarian dysfunction that cannot be addressed through other methods. The option of using donor oocytes uniquely targets infertility due to diminished ovarian reserve.

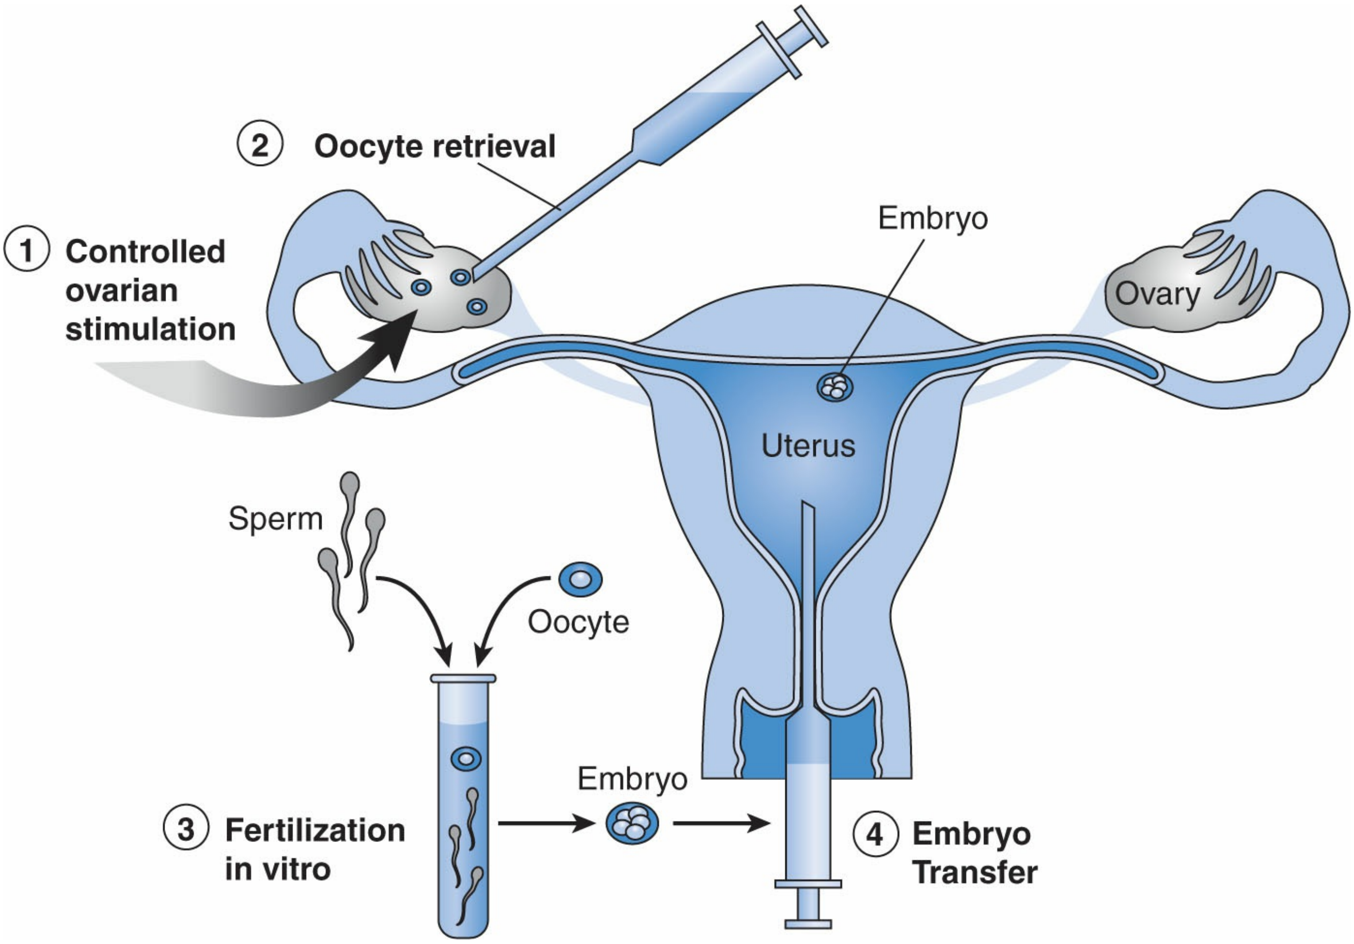

Figure 48-2 In vitro fertilization process.

CASE 48-2

QUESTION 1: F.J., a 39-year-old woman, and her 42-year-old husband are a recently married couple undergoing a comprehensive infertility evaluation after 6 months without conceiving. F.J.'s medical history is positive for seasonal allergic rhinitis, dysmenorrhea, and a history of chlamydia at age 21. Her current screen for sexually transmitted infections is negative. F.J.'s reproductive history reveals menarche at age 11, no prior pregnancies, and regular menstrual cycles approximately 30 days in length. Her body mass index is 21 kg/m^2.

There are no abnormal findings on her physical examination. She undergoes a CC challenge test and her FSH and estradiol levels on cycle day 3 are 7 mIU/mL and 46 pg/mL, respectively. The day 10 FSH is 6 mIU/mL. Her HSG shows complete occlusion of the left fallopian tube and partial occlusion of the right fallopian tube. What findings support female factor infertility?

This couple is undergoing evaluation of infertility after only 6 months without conceiving because of F.J.'s advanced age (older than 35) and history of chlamydia, which places her at increased risk of complications from pelvic inflammatory disease. The occlusion of her fallopian tubes is most likely from the chlamydial infection at age 21, which may or may not have been detected and treated at that time. Laparoscopy would be necessary to rule out any additional causes such as endometriosis. Further hysteroscopic procedures are warranted to define the location and type of obstruction and to determine whether surgical repair is feasible.[32] Her regular menstrual cycle length and history of dysmenorrhea is supportive of an ovulatory menstrual cycle and her CC challenge test shows adequate ovarian reserve, with normal levels of FSH and estradiol. She is within the normal weight range and has normal findings upon physical examination. However, further laboratory testing may be warranted to confirm normal thyroid and pituitary function and rule out findings associated with PCOS.

CASE 48-2, QUESTION 2: F.J.'s husband has normal findings upon physical examination. His semen analysis yields the following results:

Semen volume, 3 mL
Sperm number, 41 × 10^6
Sperm concentration, 18 × 10^6/mL
Sperm total motility, 35%
Sperm progressive motility, 30%
Sperm vitality, 60%
Sperm morphology, 2%

A repeat analysis produces similar results. Additional laboratory findings include:

Testosterone, 650 ng/dL
FSH, 4 mIU/mL
Prolactin, 14.2 ng/mL

What is the significance of these findings for male factor infertility and the choice of ART for this couple?

The semen analysis is significant for sperm motility and morphology values below the lower reference limit defined by the World Health Organization. The semen volume, sperm number, and vitality measurements are just above the lower reference limit (Table 48-2).[18] Interventions to improve sperm parameters typically target the underlying cause if possible, such as treatment of hyperprolactinemia or supplementation with testosterone. In some cases, sperm production can be stimulated through the use of medications that influence the hypothalamic–pituitary–testicular axis. For example, CC may improve sperm concentrations in men with hypogonadotropic hypogonadism by stimulating hypothalamic release of GnRH.

There is no consensus regarding the optimal dosage regimen, which is FDA-labeled for use in women only. Small clinical studies have examined CC in initial daily doses of 12.5 to 25 mg, in addition to alternate-day and cyclic dosing for treatment periods of several months with positive results.[33] Administration of various regimens of injectable gonadotropins (FSH, LH, or hCG) also improves pregnancy rates.[33] Given this patient's normal serum testosterone and FSH, CC or gonadotropins are not recommended therapies. His prolactin is normal as well, ruling out this potential secondary cause. In this case, there is no identifiable cause of the abnormal parameters so it is deemed idiopathic, without a known etiology.

Antioxidants such as vitamin C, vitamin E, folic acid, zinc, selenium, and L-carnitine are reported to counteract negative effects from oxidative stress on sperm. Some small studies have demonstrated improvement in sperm motility, concentration, and morphology. A systematic review documented a possible increase in live birth rates with the use of antioxidants.[34] F.J.'s husband may choose to take a daily antioxidant supplement as they move forward with other treatment modalities.

Insemination procedures are one approach to address abnormal findings on semen analysis. Bypassing the cervix and placing the sperm closer to the fallopian tubes near the time of ovulation can overcome lower sperm counts and motility issues. In regard to this couple, however, F.J. does not have patent fallopian tubes and would not be a candidate for IUI. An ART procedure will be necessary to address both female and male infertility factors.

IVF is more appropriate than gamete intrafallopian transfer and zygote intrafallopian transfer due to F.J.'s tubal findings. Although surgical repair of the obstructed fallopian tubes may be possible in some cases, many couples choose to bypass this option and pursue ART, especially when there are additional male factors.[32] F.J. will need a surgical evaluation to confirm whether this is recommended prior to proceeding to ART. F.J. is ovulatory with adequate ovarian reserve, so the use of donor oocytes is not required. Her husband's abnormal sperm parameters can be addressed through ICSI, with the option of using donor sperm in the future, if necessary.

IN VITRO FERTILIZATION

The basic steps in an IVF protocol include SO/COS, oocyte retrieval, fertilization, embryo culture, and embryo transfer. Medications are primarily used during three main stages of IVF: COS, oocyte retrieval, and luteal phase support (Table 48-5). (For a step-by-step guide to all the steps in this complex process, go to http://www.sart.org/patients/a-patients-guide-to-assisted-reproductive-technology/general-information/art-step-by-step-guide/) Treatment protocols vary widely in the medications used, dosing regimens, and timing of administration. A sample in vitro fertilization protocol representing F.J.'s experience is provided in Figure 48-3.

CASE 48-2, QUESTION 3: After the completed evaluation, the couple chooses to undergo IVF with intracytoplasmic sperm injection. Although F.J. is very excited to begin the process, she is anxious about administering the multiple injectable medications associated with the procedure. What medication regimen is recommended to initiate the IVF protocol?

Stage One: Controlled Ovarian Stimulation/Superovulation

The purpose of COS for IVF is the development of multiple follicles for oocyte retrieval. Although oocyte retrieval and fertilization can be performed during a normal ovulatory cycle without stimulation, it is more common and many times necessary to use this process.

Oral Contraceptives

Controlled ovarian stimulation for IVF is designed to manipulate follicular development for oocyte retrieval at the most optimal stage of maturation. Many protocols start with the administration of oral contraceptives for up to 28 days in the preceding menstrual cycle. This serves to control the timing of the onset of the next menses in order to plan for initiating the COS regimen.[35] This is particularly pertinent in women who have irregular or long menstrual cycles, but is also common practice in those with regular menstrual cycles. F.J. has a history of regular menstrual cycles, but is still a candidate for oral contraceptive therapy to conveniently time the remainder of the treatment course.

Table 48-5

Role of Medications in an In Vitro Fertilization Cycle

IVF Stage	Medications[a]	Role
Stage one: controlled ovarian stimulation	Oral contraceptives	Control the onset of menses and the start of controlled ovarian stimulation
	GnRH agonists or GnRH antagonists	Prevent a premature LH surge or disruption of controlled ovarian stimulation
	Gonadotropins (FSH or FSH plus LH)	Stimulate development of multiple ovarian follicles for oocyte retrieval
Stage two: oocyte retrieval	hCG	Induce final follicular maturation to prepare for oocyte retrieval
Stage three: luteal phase support	Progesterone	Maintain the endometrium for embryo transfer and implantation

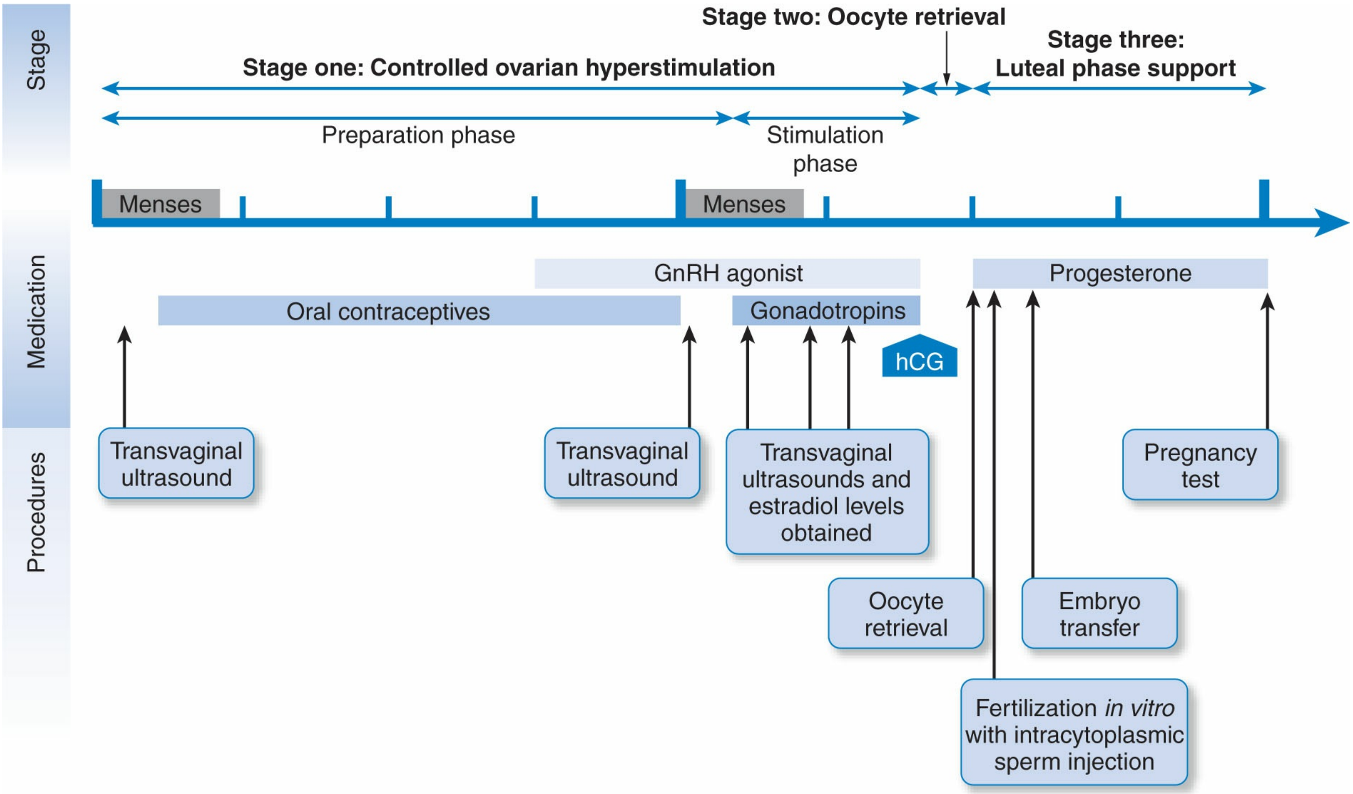
[a] This list reflects the medications most commonly used during each stage. Alternate regimens vary widely by specialist.

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

Gonadotropin-Releasing Hormone Analogs

Once the COS process begins, it can be interrupted by an endogenous surge of LH that triggers ovulation prematurely and threatens the success of the cycle. Most protocols use medications to limit the influence of any endogenous hormone levels as the cycle progresses. Gonadotropin-releasing hormone agonists have been used for this purpose for several decades. Administration of a GnRH agonist initially increases pituitary gonadotropin release, often referred to as a "flare." Continued daily administration leads to receptor downregulation and reduced pituitary secretion of LH and FSH, allowing for direct administration of the gonadotropins by injection.[36]

The most common IVF regimens in the United States use either subcutaneous leuprolide or intranasal nafarelin (Table 48-6).[23] The leuprolide formulation is often dosed in "units" using an insulin syringe to permit measurement of small volumes. Daily doses of 10 to 20 "units" correspond with 0.5 to 1 mg using the 1 mg/0.2 mL product. The depot formulations of leuprolide or goserelin acetate used for endometriosis or hormone-dependent cancers may require higher doses and longer duration of gonadotropin administration for COS.[37] Intranasal nafarelin has been studied in doses of 200 to 400 mcg twice daily.[38] Intranasal absorption can be variable depending on the administration technique, dosage interval, sneezing, or use of nasal decongestants.[39] However, studies indicate that pregnancy rates between the GnRH agonists are similar.[38]



Stage

GnRH, gonadotropin-releasing hormone; IM, Intramuscular; SC, subcutaneous.

Treatment protocols are identified by the timing of GnRH agonist administration. In a traditional “long” protocol, a GnRH agonist is initiated during the follicular or luteal phase of the preceding menstrual cycle. Once gonadotropins are initiated, the GnRH agonist is continued at half the daily dose until ovulation is stimulated. If an oral contraceptive is used for pretreatment, the GnRH agonist is often initiated within the last week of the contraceptive regimen. In a “short” protocol, a GnRH agonist is administered in conjunction with the gonadotropins for the stimulation cycle. When used in this manner, the flare, or initial increase in gonadotropin production, aids in the initial recruitment and development of follicles. The continued administration at a lower dose serves to suppress the LH surge. An “ultrashort” protocol reserves the use of the GnRH agonist for just the first 3 days of gonadotropins. The fewer injections in the shorter protocols potentially improves cost and patient convenience. Many other variations of the long and short protocols that adjust the length of GnRH agonist use, dose, and timing of discontinuation are utilized, with wide variability among clinics.[36,40]

Alternatively, the immediate suppression of gonadotropin secretion using GnRH antagonists such as cetrorelix and ganirelix allows for a shorter duration of administration and improved convenience (Table 48-6).[23] Additionally, the lack of FSH and LH flares reduces the incidence of ovarian cysts that can occur with the GnRH agonists. The GnRH antagonists are administered after the gonadotropin-induced follicular development is established, as either a higher-dose single injection or a lower-dose daily injection that is continued until ovulation is triggered.[36,40] Ganirelix is administered as a daily 250-mcg subcutaneous injection and cetrorelix is either a daily subcutaneous injection of 0.25-mg or a single 3-mg dose.[23] The timing of initiation is either "fixed" on a particular day of stimulation or "flexible" based on follicular development.[40] Available data suggest that there is no difference in pregnancy and live birth rates between GnRH agonist and antagonist protocols.[40,41]

In this case, a protocol using a GnRH agonist is chosen for F.J. For the preparation phase, an injectable (such as leuprolide) or intranasal (nafarelin) product can be used. The administration of GnRH analogs in the long protocol is associated with hot flashes, headaches, and sleep disturbances due to hypoestrogenic effects. Concurrent administration of oral contraceptives may help lessen these responses.[42] An intranasal product may appear preferable given F.J.'s concerns about injections. Local reactions at the injection site and nasal and throat irritation are adverse effects expected with the subcutaneous and intranasal routes of administration, respectively.[39,42] However, the symptoms and duration of her seasonal allergic rhinitis should be clarified because the absorption of the intranasal product can be affected by sneezing, congestion, and use of other intranasal medications. Thorough discussion and demonstration of the subcutaneous injection technique can also reduce a patient's fears regarding this route of administration. After discussion, F.J. agrees to administer leuprolide injections. Once she experiences her next menses, she will begin 21 days of an oral contraceptive. On day 16 of this regimen, she will initiate leuprolide 1 mg once daily as a subcutaneous injection in conjunction with the oral contraceptives. A calendar will be provided to help her track the daily doses.

Gonadotropins

CASE 48-2, QUESTION 4: F.J. completes the oral contraceptive regimen and starts her menses. A baseline ultrasound rules out ovarian cysts and confirms ovarian suppression. She continues daily injections of leuprolide at a dose of 0.5 mg once daily (half the initial dose) upon initiation of gonadotropins for follicular development. What is the recommended gonadotropin regimen for F.J.?

The exogenous administration of FSH alone or in combination with LH is intended to mimic the natural process of follicular recruitment and maturation. Gonadotropins are available from urinary and recombinant methods (Table 48-3).[23] Human menopausal gonadotropin (hMG) was the first gonadotropin used in the United States as early as the 1950s. The product is extracted from urine of postmenopausal women and standardized to contain 75 IU each of FSH and LH activity. Both LH and hCG are present in the preparation and contribute to the LH activity. Urofollitropin is a urinary FSH that when first marketed in the 1980s retained small amounts of LH and other urinary proteins that were not clinically active. A highly purified urofollitropin is now available that can be injected subcutaneously in place of the earlier intramuscular preparations. The development of the recombinant FSH products (follitropin alfa and follitropin beta) further expanded treatment options in the late

1990s. Although they have unique chemical structures, they result in clinically similar effects.[43]

Women with hypogonadotropic hypogonadism require administration of both FSH and LH because their low endogenous LH levels do not support follicular development. This is achieved through the administration of hMG. Women with normal pituitary function can receive injections of FSH alone, either as urofollitropin or a recombinant product. It is generally demonstrated that urinary hMG and recombinant FSH result in similar pregnancy rates, and there is no consensus recommendation for one preparation over the other.[44]

Dosage regimens for the gonadotropins are intended to promote multiple follicles for oocyte retrieval and vary widely among clinics. A common starting dose in fixed-dose protocols is 150 to 225 IU daily, with further dose adjustments made based on the status of the developing follicles. Treatment may continue for 7 to 12 days, although longer courses may be necessary depending on follicular response. If subsequent cycles are needed, the initial treatment doses are chosen based on the stimulation achieved in the first cycle.[36]

F.J. is undergoing her first cycle of IVF, so there are no data regarding prior gonadotropin response to guide the dose selection. She has no signs of hypothalamic or pituitary dysfunction so she can receive FSH alone or in combination with LH. All of the available highly purified or recombinant products require daily subcutaneous injections. Although this may be a concern for F.J., this is an advantage over earlier formulations that required intramuscular injection. All products require reconstitution of one or more vials of lyophilized powder just prior to injection except certain formulations of the recombinant follitropin alfa and beta. The two recombinant FSH formulations are available in pen injection devices that avoid the need for reconstitution and reduce the complexity of the dose preparation and injection procedure (Table 48-3).[23] Patient education should focus on product-specific instructions for storage, preparation for injection, and the correct subcutaneous injection technique. All products have patient-friendly video demonstrations or handouts available on the Internet to facilitate this process. (For helpful training videos and patient handouts that describe the dose preparation and injection technique, see **https://www.ferringfertility.com/products/**, and **https://fertilitylifelines.com/fertility-treatments/injection-instructional-videos/**.) The patient should be instructed to anticipate possible injection-site reactions as well as psychological symptoms of irritability, mood swings, and depression which may increase during this phase.[42]

After consideration of these issues, a recombinant FSH product is chosen for F.J. because of the convenience of the pen device. She will begin a dose of 225 IU of recombinant follitropin alfa injected subcutaneously once daily.

CASE 48-2, QUESTION 5: F.J. begins daily subcutaneous injections of follitropin alfa in addition to her leuprolide injections. What medication monitoring should be provided at this time?

The goal of gonadotropin therapy is to guide the development of multiple follicles for oocyte retrieval without increasing the risk for ovarian hyperstimulation syndrome (OHSS), a rare but serious complication of COS. In its most severe form, this syndrome is characterized by increased systemic vascular permeability that can result in ovarian rupture, thromboembolism, renal failure, and adult respiratory distress syndrome. The risk for this condition correlates most directly with the development of multiple ovarian follicles. Additional risk factors include younger age, low body weight, and history of PCOS. Routine monitoring of ovarian follicular development allows the clinician to maximize efficacy and reduce the risk for overstimulation.[45]

Typical monitoring includes vaginal ultrasounds and serum estradiol measurements performed every 1 to 3 days during the COS phase. The monitoring frequency increases as the follicular development advances, and the gonadotropin doses may be reduced or increased depending on the number and size of the follicles. If hyperresponse is evident, the cycle may be cancelled prior to oocyte retrieval.[45] An alternative to cycle cancellation is “coasting,” or discontinuation of gonadotropins until serial estradiol measurements show a plateau or declining trend.[45]

Once F.J. initiates therapy, she is scheduled for serum estradiol and vaginal ultrasound measurements every other day. This increases to daily monitoring on day 7 of the combination of leuprolide and follitropin alfa because the number and size of the follicles continue to increase.

Stage Two: Oocyte Retrieval

Chorionic Gonadotropin

CASE 48-2, QUESTION 6: F.J. presents for her daily monitoring on day 10 and it is determined that she is ready for oocyte retrieval. What medication regimen is recommended at this time?

Chorionic gonadotropin is administered in preparation for oocyte retrieval to simulate the effect of the physiologic LH surge on final oocyte maturation. The oocyte retrieval must be carefully timed to coincide with the completion of the oocyte maturation process, just prior to ovulation. Many clinics schedule oocyte retrieval between 34 and 36 hours after chorionic gonadotropin is injected.

Chorionic gonadotropin is available from urinary or recombinant sources. The urinary hCG product is administered as a single intramuscular injection of 5,000 to 10,000 IU.[23] Doses of 5,000 IU may be administered to patients who are deemed to be at high risk for OHSS.[45] The dose of the recombinant product is 250 mcg injected subcutaneously.[23] A single dose of a GnRH agonist is an alternate method of triggering LH release in IVF protocols that incorporate a GnRH antagonist. This approach appears to reduce the risk for OHSS, but may lower pregnancy rates.[46] F.J. received the GnRH agonist leuprolide in her prestimulation period so she would not be eligible for this approach.

Given F.J.'s concerns regarding injections and the fact that she has been administering the follitropin alfa subcutaneously, it is prudent to continue with this route of administration. F.J. is instructed to inject a single 250-mcg dose of recombinant chorionic gonadotropin subcutaneously. She will discontinue leuprolide and follitropin alfa at this time.

Ovarian Hyperstimulation Syndrome

CASE 48-2, QUESTION 7: F.J. undergoes a transvaginal oocyte retrieval procedure 36 hours after the administration of recombinant chorionic gonadotropin and there are nine oocytes available for fertilization. What additional counseling is recommended for F.J. after the oocyte retrieval?

As previously described, OHSS is a rare complication associated with COS. Careful monitoring of estradiol levels and follicular development on ultrasound limits the incidence. However, if symptoms develop, it is typically within 1 to 2 weeks after oocyte retrieval. It is generally categorized as mild, moderate, or severe, and can occur early (within 9 days after oocyte retrieval) or late (after 10 days, often associated with a pregnancy).[45,47] The clinical signs of OHSS are thought to result from increased capillary permeability due to high levels of vascular endothelial growth factor. However, the specific underlying pathology is poorly understood. A mild presentation of OHSS consists primarily of gastrointestinal symptoms (abdominal pain, nausea, diarrhea, bloating) or weight gain, especially abdominal distension. A patient experiencing these symptoms will be instructed to avoid physical activity, maintain oral fluid intake of at least 1 L/day, and monitor daily weights and urine output. The patient should report any weight gain of 2 lb or more to allow for more intensive outpatient monitoring of liver and renal function, electrolytes, and hematologic parameters. If the condition progresses, the patient may require hospitalization for monitoring and treatment of severe outcomes such as thromboembolism, renal failure, pulmonary distress, or ovarian rupture.[45]

There were no initial indications of hyperstimulation during F.J.'s COS regimen, so she will be instructed to monitor for signs of OHSS during the 2 weeks after oocyte retrieval. She should notify her physician if she experiences gastrointestinal symptoms or weight gain, even if the symptoms are mild. This will facilitate early monitoring to maximize safety during the remainder of the IVF process.

Stage Three: Luteal Phase Support

Progesterone

CASE 48-2, QUESTION 8: After the oocyte retrieval, F.J. is in need of a regimen for luteal phase support. Which agent should be selected?

Supplemental progesterone is administered immediately after oocyte retrieval to provide additional "luteal phase support" during IVF. The luteal phase of the menstrual cycle (Fig. 48-1) is dominated by progesterone released by the corpus luteum that prepares the endometrium for implantation of the fertilized ovum. The disruption of follicles during the oocyte retrieval process delays production of progesterone, necessitating supplementation. Additionally, cycles that utilize a GnRH agonist may be complicated by residual inhibition of pituitary LH secretion and progesterone production into the luteal phase.[48]

Progesterone is available in oral, vaginal, or injectable formulations (Table 48-7).[23] Intramuscular injection of progesterone in oil in a daily dose of 50 mg was the first method used for supplementation and continues to be widely used. However, alternatives to progesterone in oil have been sought due to frequent reports of rash and discomfort at the injection site.[49]

Vaginal progesterone preparations have gained popularity for luteal phase support due to ease of administration and avoidance of injection-site reactions. The 8% progesterone vaginal gel and the 100 mg vaginal insert are the only commercially available FDA-labeled preparations for use in ART procedures. The gel is administered as one 90-mg applicator once or twice daily. The dose of the vaginal insert is 100 mg either twice a day (every 12 hours) or 3 times a day (every 8 hours).[48–50] Patient education should focus on the correct technique for intravaginal administration. Both products utilize a disposable applicator to facilitate correct placement. (Detailed patient instructions are provided by both manufacturers. https://www.ferringfertility.com/products/endometrin/ and https://www.allergan.com/assets/pdf/crinone_pi.) The vaginal preparations may cause local irritation and vaginal discharge, although the vaginal gel is generally associated with less discharge than the inserts or suppositories. Clinical studies suggest no difference in pregnancy rates between vaginal and intramuscular formulations, so clinician and patient preferences often dictate the selection.[48–50]

Table 48-7

Commercially Available Progesterone Products Used in Assisted Reproductive Technology

Product Name	Strength/Dosage Form	Route of Administration
Crinone	8% vaginal gel[a]	Vaginal
Endometrin	100-mg vaginal insert[a]	Vaginal

FIRST-Progesterone VGS	50-, 100-, 200-, 400-mg vaginal suppository (compounding kit)	Vaginal
Progesterone	50 mg/mL (oil)	Intramuscular
Prometrium/micronized progesterone	100-, 200-mg capsule	Oral

[a] FDA-labeled for luteal phase support.

Source: Facts & Comparisons eAnswers. https://fco.factsandcomparisons.com/lco/action/search?q=crinone&t=name; Accessed June 14, 2017.

Oral formulations are not recommended for the purpose of luteal phase support with ART due to lower absorption and reduced pregnancy rates.[48] Compounded formulations are widely available, including oral micronized progesterone and progesterone vaginal suppositories, gels, and creams. In some cases, patients are instructed to insert oral progesterone formulations intravaginally.

Progesterone is initiated after oocyte retrieval until a pregnancy test is performed and then continued until at least 8- to 10-week gestation.[48] Data suggest that there are no significant risks to the mother or fetus from supplemental progesterone during this time period.[50]

Luteal phase support after oocyte retrieval is important for F.J. because she received a GnRH agonist in her long cycle protocol. Because the efficacy of the parenteral and vaginal formulations is similar, the patient chooses the vaginal route to avoid further injections. She determines that she is most comfortable with 8% progesterone vaginal gel applied once daily and is given instructions regarding the appropriate administration technique.

Embryo Transfer

CASE 48-2, QUESTION 9: The in vitro fertilization process using intracytoplasmic sperm injection yields four cleavage-stage embryos. What considerations are necessary for embryo transfer?

After fertilization, timing of the embryo transfer into the uterus depends on the stage of development. Cleavage-stage embryos are transferred 2 to 3 days postfertilization, whereas embryos in the blastocyst stage are transferred at day 5 or 6.[51] (To reference a tool that gives a representation of the embryo at different stages, see http://visembryo.com/baby/pregnancy1.html.) The number of embryos placed during this process must balance the risks of a multiple gestation pregnancy with the likelihood of successful implantation.

Multiple gestation pregnancies are associated with increased maternal and neonatal morbidity. The mother is at risk for complications such as premature labor, pregnancy-induced hypertension, and gestational diabetes. Preterm labor occurs in approximately 15% of single gestation pregnancies compared with 75% of triplet pregnancies. The neonates are more likely to experience fetal growth restriction and require intensive care for pulmonary, gastrointestinal, and neurologic complications.[22] Additional stressors include the financial and psychosocial implications of raising children with complex medical needs that may persist beyond infancy.[22]

F.J. is 39 years old experiencing her first cycle of IVF. The ASRM has developed embryo transfer recommendations to limit high-order multiple pregnancies (three or more implanted embryos). Based upon her age, if the embryos are judged to have good quality morphology, no more than three cleavage-stage or two blastocysts should be transferred according to ASRM guidelines.[51] A pregnancy test will be performed 9 to 12 days after the embryo transfer to determine the outcome of the cycle.

Long-Term Considerations

Alternate Protocols

CASE 48-2, QUESTION 10: After careful consideration, the couple decides to transfer two cleavage-stage embryos and reserve two for cryopreservation. Unfortunately, the embryo transfer procedure is unsuccessful and the couple plans to pursue a second procedure. What considerations are necessary for future cycles?

Determining an action plan for subsequent procedures requires a thorough evaluation of the response to therapy during the first cycle. If COS is repeated for oocyte retrieval, hormone levels, follicular development, fertilization rates, and numbers of viable embryos are all considered to determine whether dosage adjustments or alternate medication protocols are necessary.

In this case, F.J. experienced adequate follicular development for oocyte retrieval without signs of OHSS. The fertilization procedure was successful and two embryos were cryopreserved for future procedures. The couple can choose to avoid another stimulation process for oocyte removal and move to frozen embryo transfer. Medications remain important for the frozen embryo transfer process, which can occur in a natural cycle or a cycle induced through the use of estrogen and progesterone, with or without GnRH agonists.[52]

Beyond planning the actual protocol, the long-term safety of any repeated medication exposure as well as the psychosocial effects of continuing therapy must be considered. The time needed to gather available information and weigh all considerations will be specific to each couple.

Psychosocial Issues

The financial impact of ART is substantial. The ASRM cites the average cost of an IVF cycle in the United States to be between $10,000 - $15,000.[53] Costs vary widely between clinics and many offer financial counseling and payment packages to facilitate treatment. Additionally, the psychological stress of the diagnosis and treatment of infertility must be considered at all stages. There is an observed fluctuation of mood during the course of an IVF cycle, with higher stress points identified at oocyte retrieval and pregnancy testing. This is complicated by potential side effects of medications as well as the baseline mental health of the couple.[54] For couples who undergo successive ART procedures, repeated failures are commonly accompanied by feelings of grief and frustration, and psychological distress is often the reason for discontinuing treatments. Levels of emotional distress, including symptoms of depression and anxiety, can increase with each unsuccessful cycle. This response appears to remit immediately with a successful pregnancy, but in those who continue to be unsuccessful, symptoms can still be significant even 6 months post-treatment.[55]

This couple should be offered individual counseling and social support that extends beyond the initial pretreatment consultation to promote positive outcomes.[56] There are several patient-focused resources for informational fact sheets and videos highlighting the financial, medical, and psychosocial issues of infertility (Table 48-8).

Obstetric Drug Therapy

Trisha LaPointe

	CORE PRINCIPLES	CHAPTER CASES
1	The timing and quality of prenatal care can influence an infant's health and survival. Early comprehensive care can promote healthier pregnancies through early detection of risk factors, disease state management, and encouragement of healthy behaviors.	**Case 49-1 (Questions 1, 2)**
2	Important physiologic changes occur in almost all maternal organs during pregnancy to support the growth and development of the fetus.	**Case 49-1 (Question 4)**
3	Drug use during pregnancy presents a significant challenge to clinicians because of the potential adverse effect on the embryo, fetus, and newborn. A thorough assessment, including knowledge of the teratogenic potential of the drug, the critical period of exposure, and magnitude of risk, must be compared with the background risk.	**Case 49-1 (Question 5)**
4	Gastrointestinal (GI) disturbances such as nausea and vomiting and gastric reflux that occur during pregnancy are common. Treatments include intravenous (IV) hydration, pyridoxine (vitamin B_6), antihistamines, and antiemetics for nausea and vomiting. Calcium carbonate, H_2-receptor antagonists, and proton-pump inhibitors may be used for common complaints from reflux.	**Case 49-1 (Questions 6-10)**
5	Urinary tract infections can frequently occur during pregnancy and can easily be treated with nitrofurantoin, cephalexin, or penicillin if cultures are sensitive.	**Case 49-1 (Questions 11)**
6	Diabetes mellitus is the most common maternal medical complication during pregnancy. Tight glycemic control can minimize neonatal and fetal morbidity and mortality associated with diabetic embryopathy.	**Case 49-2 (Questions 1–4),** **Case 49-3 (Questions 1, 2),** **Case 49-4 (Questions 1–4)**
7	Women with pregnancy-associated hypertension can be grouped into the following categories: chronic hypertension, preeclampsia–eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.	**Case 49-5 (Questions 1–13)**
8	The induction of labor involves the artificial stimulation of uterine contractions that lead to labor and delivery.	**Case 49-6 (Questions 1–5)**
9	Premature birth is the leading cause of neonatal mortality (infant death <1 month of age). Tocolytic therapy to stop contractions, corticosteroids	**Case 49-7 (Questions 1–7)**

	for fetal lung maturity, and antibiotics for preterm premature rupture of membranes can help to prolong the pregnancy.	
⑩	Infectious complications, including bacterial vaginosis and urinary tract infections, can lead to preterm labor. Chorioamnionitis, an infection of the chorion and amnion usually diagnosed during labor with elevations in temperature, should be treated with IV antibiotics until delivery. Human immunodeficiency virus (HIV)-infected mothers should receive IV zidovudine and continue their antiretroviral regimens during labor.	**Case 49-7 (Questions 8–11), Case 49-8 (Questions 1, 2)**
⑪	Obstetric postpartum hemorrhage is one of the top three causes of maternal mortality in the United States. Pharmacologic therapy for uterine atony includes oxytocin, methylergonovine, carboprost, misoprostol, and dinoprostone.	**Case 49-8 (Questions 3, 4)**

⑫	Alloimmunization occurs when an Rh D-negative mother becomes immunized after exposure to fetal erythrocytes that carry the D antigen. Rh$_O$(D) immune globulin should be given to all mothers who are Rh D negative at 28 weeks’ gestation.	**Case 49-9 (Questions 1–5)**

LACTATION AND DRUGS IN BREAST MILK

①	Breast milk is recognized as the optimal source of nutrition for infants, with documented benefits not only to infants but also to mothers, families, and societies, and breast-feeding should be encouraged if possible.	**Case 49-10 (Questions 1, 2), Case 49-11 (Question 1)**
②	Most drugs are excreted in the breast milk. The pharmacologic and adverse effects on the infant will be determined by the extent of oral bioavailability, distribution, metabolism, and rate of elimination. A milk-to-plasma ratio can be used to estimate the drug concentration in milk. The relative infant dose (RID) can be calculated to estimate the infant’s exposure based on volume of milk ingested.	**Case 49-8 (Question 2), Case 49-12 (Question 1), Case 49-13 (Question 1)**

PREGNANCY

Definitions

PARITY AND GRAVIDA

Parity and gravida are terms used to describe a pregnant woman. Parity is the number of deliveries after 20 weeks’ gestation. Parity is independent of the number of fetuses delivered (live or stillborn, single fetus, or twins) or the method of delivery. Gravida refers to the number of pregnancies a woman has had regardless of the outcome. For example, a woman who is currently pregnant and has previously delivered one set of twins and had two spontaneous abortions is described as a gravida 4, para 1 (G4, P1).

TRIMESTERS OF PREGNANCY

The average pregnancy is approximately 40 weeks when calculated from the first day of the LMP. Pregnancy is typically divided into three trimesters, approximately 13 to 14 weeks each.[1] The first trimester includes the critical period of organogenesis, the time in which most of the vital organs are developing, which occurs between weeks 5 and 10. The time between the end of the 20th week of gestation and the end of the 28th day after birth is considered the perinatal period.

DELIVERY

Depending on the gestational age at the time of delivery, the result can be an abortion, preterm, term, or post-term birth. An abortion is a delivery before 20 weeks' gestation. A term infant is a fetus delivered between 37 and 42 weeks' gestation. A preterm birth is one occurring between 20 and 37 weeks' gestation, and a post-term (postmaturity) birth occurs after the beginning of 42 weeks' gestation. Parturition refers to labor, and the puerperium is the 6 to 8 weeks after delivery.

Preconceptional Care

CASE 49-1

QUESTION 1: S.C. is a 29-year-old, G1, P1 woman who is interested in becoming pregnant. Her past medical history is significant for hypothyroidism. She currently is taking levothyroxine 88 mcg by mouth daily. Provide appropriate counseling to S.C. with regard to preconceptional care.

It is estimated that 3.9 million live births were registered in the United States in 2013, with an estimated 70.8% of women beginning prenatal care in the first trimester. This can be contributed to several statewide initiatives to increase education and access to prenatal care.[2] Although much improved, prenatal care is still not easily accessible to all women. Early comprehensive care can promote healthier pregnancies through early detection of risk factors, disease state management, and encouragement of healthy behaviors, and will help to ensure normal fetal organogenesis. Appropriate preconception counseling and treatment of women with preexisting high-risk medical conditions, such as diabetes, hypertension, and epilepsy, can greatly improve pregnancy outcomes. In 2013, the mortality rate in the United States (from birth through the first year of life) for infants of mothers beginning prenatal care in the first trimester was 5.96/1,000 live births.[3]

S.C. should see her primary-care provider for regular physical examinations and evaluation of her thyroid function before becoming pregnant. Her first prenatal visit should generally occur by 8 weeks' gestational age when she becomes pregnant.[4]

Vitamins and Mineral Supplementation

CASE 49-1, QUESTION 2: S.C. asks you to recommend vitamin and mineral supplementation and to provide guidance on when should she begin taking these vitamins and minerals.

A balanced diet that provides S.C. with multiple B vitamins, oil-soluble vitamins (A, E, D, and K), folic acid, and minerals (iron, calcium, phosphorus, magnesium, iodine, zinc) should be encouraged. S.C. should be started on a prenatal multivitamin if she has not yet started taking one. Prenatal vitamins should be taken months before conception to ensure that proper nutritional requirements are met during critical periods of organogenesis and fetal growth.

IRON REQUIREMENTS

Iron requirements increase during pregnancy because of maternal blood volume expansion, fetal needs, placenta and cord needs, and blood loss at the time of delivery.[5] Maternal iron deficiency can cause anemia during infancy, spontaneous abortion, premature delivery, and delivery of a low-birth-weight infant, and is associated with low neonatal iron stores.[5,6]

A woman needs about 18 to 21 mg of iron/day during pregnancy; the body compensates by increasing iron absorption from the GI tract by about 15% to 50%.[5] The average diet of women

---

in the United States does not meet these requirements because only about 6 mg of iron is absorbed from 1,000 kcal of food. In addition, some women may already have inadequate body stores of iron before pregnancy. For these reasons, the Centers for Disease Control and Prevention recommends screening for iron deficiency in pregnancy in addition to universal iron supplementation except when genetic conditions such as hemochromatosis are present.[7] Prenatal vitamins usually contain 30 to 60 mg of elemental iron. Women with iron deficiency anemia should be given 60 to 120 mg of elemental iron daily. Iron deficiency anemia during pregnancy generally is associated with a hemoglobin and hematocrit less than 11 mg/dL and less than 33%, respectively, during the first and third trimesters or less than 10.5 mg/dL and less than 32%, respectively, during the second trimester. The classic morphologic changes observed in the erythrocytes in iron deficiency outside of pregnancy, hypochromia, and microcytosis are not prominent in pregnant women. Serum ferritin, however, is low, which has the highest sensitivity and specificity for diagnosing iron deficiency.[6] S.C.'s hemoglobin and hematocrit should be assessed now and again at 26 to 28 weeks' gestation. If her hemoglobin and hematocrit are normal, the amount of iron in her prenatal vitamin should be sufficient.

FOLATE REQUIREMENTS

Folic acid is essential in the synthesis of DNA and RNA. Pregnant women who take 0.4 to 0.8 mg of folic acid daily during the first trimester of pregnancy are significantly less likely to have a child with neural tube defects (NTDs), such as spina bifida and anencephaly.[8,9] NTD can lead to stillbirth, neonatal death, or serious disabilities. Approximately 4,000 pregnancies in the United States are affected by NTD each year.[9]

NTDs develop within the first month of pregnancy at a time when many women are unaware of their pregnancy.[9,10] In 1992, the US Public Health Service recommended that all women with childbearing potential should consume 0.4 mg/day of folic acid to reduce the risk of an NTD-affected pregnancy.[11]

It may be difficult to meet the recommended daily allowance (RDA) for folic acid because foods contain only a small amount of this vitamin; overcooking and high-fiber diets also can reduce the amount of available folic acid from food. Most prenatal vitamins contain 0.8 to 1 mg of folic acid.

Folic acid supplementation is especially important in women with a history of infants born with NTD. Women who have had an NTD-affected pregnancy should receive genetic counseling because they have a 2% to 3% risk of having another such outcome. Women with previous NTD-affected pregnancies who plan another pregnancy should take 4 mg/day of folic acid at least 1 month before conception and through the first 3 months of pregnancy.[11]

Women who require 4 mg/day of folic acid should be prescribed folic acid tablets as an addition to combination prenatal multivitamins (which contain folic acid), rather than just increasing the number of multivitamin tablets. When several fixed-combination multivitamin tablets are taken daily, the mother could be exposed to a potentially teratogenic dose of vitamin A. High doses of folic acid do not prevent NTD better than 0.4 mg/day in women without a previous history of NTD-affected pregnancies and may complicate the diagnosis of a vitamin B_{12} deficiency.[9]

S.C. should be counseled about the risks for NTD, and given she has no history of NTD, she should receive adequate folic acid during the remainder of her pregnancy from a daily prenatal vitamin.

CALCIUM REQUIREMENTS

Calcium is needed during pregnancy for adequate mineralization of the fetal skeleton and teeth, especially during the third trimester when teeth are formed and skeletal growth is greatest. The RDA for calcium during pregnancy is 1,000 mg/day for women of 19 years and older, and 1,300 mg/day for teenagers younger than the age of 19.[12] Large maternal stores can provide calcium if dietary intake is inadequate; however, depleting maternal stores may put S.C. at risk for osteoporosis later in life. Foods rich in calcium (e.g., milk, cheese, yogurt, legumes, nuts, dried fruits) or calcium supplements can be used to meet the calcium RDA.

Commercially Available Home Pregnancy Tests

CASE 49-1, QUESTION 3: S.C starts her prenatal vitamins that contain iron and folic acid immediately. Two months have passed, and now S.C. believes that she may be pregnant because per period is a couple of weeks late. She requests your assistance in selecting an over-the-counter commercially available home pregnancy test. How do these home pregnancy tests work and how should S.C. be counseled?

Commercially available home pregnancy tests are enzyme immunoassays with monoclonal or polyclonal antibodies that bind to hCG in the urine.[13] hCG is detected in the maternal circulation and urine approximately 8 to 10 days after conception.[14] Concentrations in the urine closely parallel those in the maternal blood. The hCG serum concentrations increase rapidly, doubling every 2 days. Peak concentrations are achieved at 60 to 70 days of pregnancy. Thereafter, hCG concentrations decline and reach a low by approximately 120 days, at which point concentrations are maintained for the remainder of the pregnancy.[14]

hCG is composed of an α- and a β-subunit. The α-subunit is identical to the α-subunit of other pituitary hormones (e.g., follicle-stimulating hormone, luteinizing hormone, thyroid-stimulating hormone); however, the β-subunit is specific to hCG. Pregnancy tests specific for this β-subunit are useful diagnostic tests for confirming pregnancy.[1] They can provide accurate results within 1 to 2 weeks after ovulation.[1,13] Several kits are available. The tests can be performed privately and quickly and are easily interpreted. The results are obtained rapidly—within 1 and 5 minutes—and are highly accurate when performed at the start of the first missed menstrual period. Although home pregnancy tests are reportedly 98% to 100% accurate when used correctly, consumer studies have documented accuracy rates as low as 50% to 75% if product directions are not precisely followed.[13] Many home pregnancy tests include a second test, which should be repeated at a specified time after the first negative test result.

S.C. should purchase a product containing two tests and follow the instructions carefully. If the first test result is negative, S.C. should repeat the test in 1 week if she has not started menstruating. False-negative results occur when testing is done before the first day of a missed period or if the urine is not at room temperature.[13] False-negative results can also occur with an ectopic (outside the uterus) pregnancy or in women with ovarian cysts and in those receiving menotropins or chorionic gonadotropin.[13] False-positive pregnancy test results are rare, but can occur with serum testing if the woman has circulating heterophilic antibodies directed against the animal-derived antigen use in pregnancy tests. These antibodies will not interfere with urine assays, however, as they are not present in urine.[15]

S.C.'s home pregnancy test is positive. Because she is pregnant she should be counseled on the possible fetal effects of any medications or herbal products she may be taking and advised to see her primary-care provider as soon as possible.

Pregnancy-Induced Pharmacokinetic Changes

CASE 49-1, QUESTION 4: S.C. is now 6 weeks pregnant. She is concerned about any possible changes that might occur with her medications (levothyroxine 88 mcg orally [PO] daily, prenatal vitamins). Describe pregnancy-induced pharmacokinetic changes that might occur that will affect her medication use and appropriate monitoring.

Important physiologic changes occur in almost all maternal organs during pregnancy to support the growth and development of the fetus. These physiologic changes affect the cardiovascular, respiratory, and GI systems; plasma volume, renal function, and hepatic enzymes can alter the absorption, distribution, metabolism, and elimination of drugs.[16] Alterations in the pharmacokinetics of drugs are influenced by mainly by two factors: (a) maternal physiologic changes and (b) the effects of the placental–fetal compartment.[17]

ABSORPTION

Pregnancy-induced changes affecting drug absorption are (a) a decrease in intestinal motility owing to smooth muscle relaxation by progesterone, resulting in a 30% to 50% increase of gastric and intestinal emptying times; (b) a 40% decrease in gastric acidity, which increases gastric pH; and (c) altered bioavailability or absorption attributable to increased incidence of nausea and vomiting. Bioavailability may be increased for acid-labile drugs and decreased for drugs that require acid medium for stability. Prolonged gastric and intestinal emptying times may decrease the maximum concentration (C_{max}) of a drug and the time to reach C_{max}, whereas the increased intestinal transit time may increase the area under the curve (AUC) and bioavailability of a drug. In contrast, pregnancy-induced vomiting may decrease the amount of drug ingested; it is therefore better to schedule medications during the evening when the incidence of nausea and vomiting is lower, or to use the rectal route for drug administration. In summary, the effect of pregnancy on drug absorption is variable and depends greatly on the physicochemical properties of the drug.[17] Increased blood flow to the maternal skin, which helps dissipate fetal heat production, may also increase the absorption of a topically (transdermal) administered medication.[16]

DISTRIBUTION

Changes in protein binding and increased plasma volume can theoretically increase the apparent volume of distribution (V_d) of drugs during pregnancy. Plasma volume increases by 6 to 8 weeks' gestation and continues to expand to 40% to 50% above pregnancy volumes by 32 to 34 weeks' gestation.[16,17] Plasma volume expands even more with multiple gestations. The total body water (TBW) increases by 8 L; 40% of this increase can be attributable to the mother and 60% to the fetal–placental unit. This increase in TBW necessitates larger loading doses of water-soluble drugs (e.g., aminoglycosides) because of the increase in Vd. A decrease in the C_{max} would be expected.

Plasma albumin concentrations decrease during pregnancy, mostly because of dilution by the increased plasma volume.[16,17] Albumin concentrations may also be decreased as a result of decreased synthesis or increased catabolism.[16] In addition, increased concentrations of steroid and placental hormones may decrease protein-binding sites for drugs.[18] These changes in protein binding generally result in decreased protein binding, increased free fraction (f_u) of drugs, and increased clearance of drugs when clearance is dependent on f_u (e.g., valproic acid, carbamazepine).[18] When both f_u and intrinsic clearance are increased as is the case with increased cytochrome P-450 enzyme activity, both the total and free concentrations are decreased (e.g., phenytoin, phenobarbital).[19] Total protein and α_1-acid glycoprotein concentrations remain fairly unchanged.

METABOLISM

Protein binding, activity of hepatic enzymes, and liver blood flow determine the hepatic clearance of drugs. Increases in estrogen and progesterone during pregnancy affect the hepatic metabolism by stimulating or decreasing different hepatic enzymes of the cytochrome P-450 (CYP) system.[20] CYP3A4 and CYP2D6 activities are increased during pregnancy, which results in increased metabolism of certain drugs such as phenytoin.[17,20] On the other hand, CYP1A2, xanthine oxidase, and N-acetyltransferase activity are decreased, resulting in reduced hepatic elimination of drugs such as theophylline and caffeine.[19,21] The clearance of caffeine can be decreased by 70%.[21] Hepatic blood flow as a percentage of the cardiac output is decreased; however, the absolute rate (in L/minute) remains unchanged.[16] The activity of nonhepatic enzymes (e.g., plasma cholinesterase) is also decreased.[19] The extent of the effect on drug therapy of these hepatic physiologic changes during pregnancy is difficult to quantify.

ELIMINATION

The glomerular filtration rate (GFR) begins to rise in the first half of the first trimester and increases by 50% by the beginning of the second trimester.[19] Renal blood flow also increases by 25% to 50% early during gestation. As a result, renal drug excretion (e.g., β-lactams, enoxaparin, digoxin) can increase.[17] This increase in GFR necessitates dosage adjustments up to 20% to 65% for renally excreted drugs throughout pregnancy to maintain therapeutic concentrations.[20] The increased cardiac output and regional blood flow (e.g., renal blood flow) primarily are caused by increased stroke volume and increased heart rate, which can increase drug distribution and drug excretion.

During pregnancy, the serum creatinine concentration is lower because of the increased GFR, resulting in normal serum creatinine values of 0.3 to 0.7 mg/dL in the first and second trimesters.[20] A normal value for serum creatinine in nonpregnant adults is 0.6 to 1.2 mg/dL.[22] Similar changes occur with serum urea nitrogen and uric acid (UA) concentrations. These differences have important implications when assessing renal function during pregnancy. A serum creatinine indicative of normal renal function in a nonpregnant woman may be indicative of renal insufficiency in a woman who is pregnant in her third trimester.

PLACENTAL–FETAL COMPARTMENT EFFECT

Maternal and fetal drug concentrations are dependent on the amount of drug that crosses the placenta, the extent of metabolism by the placenta, and fetal distribution and elimination of drug (Fig. 49-1).[17,20] Diffusion across the placenta is the main mechanism of drug transfer; nonionized lipophilic substances are more readily transferred, whereas less lipid-soluble (e.g., ionized) substances less readily cross the placenta.[17] Highly protein-bound or large-molecular-weight drugs (e.g., heparin and insulin) do not cross the placenta. Both the immature fetal liver and placenta can metabolize drugs. Fetal drug accumulation can be problematic secondary to limited metabolic enzymatic activity along with the concern that approximately half of the blood flow from the umbilical vein bypasses the fetal liver and goes to the cardiac and cerebral circulations.[17] Another mechanism that can also lead to prolonged effects of drugs in the fetal compartment is ion trapping. This phenomenon occurs because the fetal plasma pH is more acidic than the maternal plasma, causing weak bases (e.g., usually nonionized and lipophilic substances) to diffuse across the placental barrier and become ionized in the more acidic fetal blood. The net effect is movement of drugs from the maternal to fetal compartment. This equilibrium between the maternal and fetal compartments becomes important when therapeutic fetal drug concentrations are desired (e.g., digoxin therapy for intrauterine fetal arrhythmias). Drugs are eliminated by the fetus primarily through diffusion back to the maternal compartment. As the fetal kidney matures, metabolites of drugs are excreted into the amniotic fluid.[17]

S.C.'s thyroid function should be checked regularly to assess the need for an increase in her levothyroxine dosage. During S.C.'s pregnancy, an increase in the Vd of thyroid hormones in the vascular, hepatic, and fetal–placental units, an increase in thyroxine-binding globulin resulting from a rise in estrogen, and an increase in placental transport and maternal metabolism of thyroxine will occur.[22] Most women with hypothyroidism who are taking oral thyroid hormones before pregnancy, similar to S.C., will require an increase in their dosage by about 30% to 50% throughout their pregnancy and then will need decreased dose adjustments postpartum.[22]

TERATOGENICITY

CASE 49-1, QUESTION 5: S.C. is currently 8 weeks pregnant and has become increasingly concerned about her medication use during pregnancy and the risk of birth defects. How should S.C. be counseled regarding the teratogenicity potential of levothyroxine use during pregnancy?

Prevalence of Congenital Malformations

The largest concern with medication use during pregnancy is the risk of congenital malformations, defined as "structural abnormalities of prenatal origin that are present at birth and that seriously interfere with viability or physical well-being."[23] Congenital anomalies or birth defects are estimated to occur in 120,000 babies born per year.[10] Some drug-induced defects relate to changes in functions or conditions that are not structural abnormalities (e.g., mental retardation, central nervous system [CNS] depression, deafness, tumors, or biochemical changes).[24] The broader term congenital anomalies include the four major manifestations of abnormal fetal development, which include growth alterations, functional deficits, structural malformations, and fetal death.[25]

The background incidence of birth defects in the general population must be taken into consideration when interpreting the risk of drug-induced birth defects. The prevalence of major congenital malformations discovered at or shortly after birth in the general population is approximately 3%.[25] This number has been derived from large epidemiologic studies completed during the past several decades and depends on how terms are defined (e.g., major versus minor congenital malformations), the thoroughness with which the infant is examined, and how long the exposed person is followed after birth.[25] The collection of malformations data is a complicated task subject to numerous errors and biases. Some studies examined only “significant anomalies,” others “major malformations,” whereas still others reported only “live births” or “single births” or “birth weights greater than 500 g.” Stillbirths and spontaneous abortions, both often associated with congenital malformations, often were excluded from epidemiologic data. Neurodevelopmental delays and growth retardation also are potential long-term effects that will not be diagnosed in the immediate postpartum period. The prevalence of congenital anomalies is likely greater than 3% if minor anomalies and long-term adverse effects are considered.

Despite the significant impact of drug-induced birth defects, it is difficult and unethical to conduct randomized, controlled trials to assess the risk of fetal exposure to drugs in humans. Much of the data available are derived from epidemiologic studies, anecdotal experiences in humans, and animal studies. Because birth defects are species-specific and influenced by many factors including genetic predisposition, the data must be carefully interpreted and the results not overgeneralized.

Causes of Malformations

CLASSIFICATION

Causes of congenital malformations are generally classified into one of five categories: (a) monogenic origin, (b) chromosomal abnormalities, (c) multifactorial inheritance, (d) environmental factors, and (e) unknown.[25] Single gene- and chromosomal-related defects account for approximately 25% of all congenital malformations in live-born infants (monogenetic, 7.5%–20%; chromosomal, 5%–6%).[24–26] Multifactorial inheritance refers to defects that are polygenic in origin; it has an environmental component. One surveillance program estimated that this interaction between genetic and environmental factors causes 23% of defects.[26] Congenital dislocation of the hip is an example of a defect in this category: The depths of the acetabular socket and joint laxity are genetically determined, and a frank breech malposition is one of the environmental factors.[27] In most cases, however, the environmental factors in multifactorial inheritance are unknown.

Environmental factors account for approximately 10% of malformations.[28] These include maternal conditions, mechanical effects, chemicals and drugs, and certain infectious agents. Maternal diseases associated with malformations include diabetes, phenylketonuria, virilizing tumors, and maternal hyperthermia. About 9% (range, 6.6%–13.0%) of infants of diabetic mothers develop major congenital defects, primarily consisting of cardiovascular, neural tube, and skeletal malformations.[29] Mechanical effects, such as intrauterine compression and abnormal cord constriction, may result in fetal deformations.[28,29]

Probably, the best known of the teratogenic viruses is rubella, which can cause a fetal rubella syndrome consisting of cataracts, heart disease, and deafness.[30] In utero exposure to rubella in the first trimester can cause defects in up to 85% of fetuses. Cytomegalovirus infection occurs in 0.5% to 1.5% of newborns in the United States, resulting in deafness and mental retardation in 5% to 10% of these infants.[24] Characteristics of cytomegalic inclusion disease, the syndrome produced by cytomegalovirus, include intrauterine growth restriction (IUGR), microcephaly, and at times chorioretinitis, seizures, blindness, and optic atrophy.

Herpes simplex 1 and 2 and varicella are also associated with malformations.[28]

The protozoan generally accepted as a teratogen is Toxoplasma gondii which may be present in cat litter.[24] Most infants infected with T. gondii show no symptoms and develop normally. When toxicity does occur, the anomalies may consist of hepatosplenomegaly, icterus, maculopapular rash, chorioretinitis, cerebral calcifications, and hydrocephalus or microcephalous.[31] Because of the possible presence of T. gondii in cat litter, women should avoid cleaning or touching cat litter while pregnant. Treponema pallidum (syphilis) can cross the placenta and cause congenital syphilis as well as other defects, such as hydrocephaly, chorioretinitis, and optic atrophy.[30] In utero exposure to syphilis after the fourth month of pregnancy is associated with higher risk.

The final category, defects of unknown cause, comprises the greatest percentage of congenital malformations, accounting for about 60% to 65% of the total.[26]

Medication Use in Pregnancy and Teratogenicity

The term teratogen is used to denote an agent that has the potential under certain exposure conditions to produce abnormal development in the fetus.[25] Many women have the general perception that use of any medication during a pregnancy can harm the developing fetus.[22] This thought may lead to consideration of terminating wanted pregnancies or withholding necessary drug therapy during the course of the pregnancy. The extent to which a drug will affect the development of the fetus depends on the physical and chemical properties of the drug as well as the dose, duration, route, and timing of exposure and the genetic composition and biologic susceptibility of the mother and fetus.[33] Numerous drugs have been associated with congenital anomalies, but only in a few cases has a consensus been reached that a specific agent is teratogenic. Table 49-1[34–36] lists those agents generally considered or suspected to be proven human teratogens. Not all these teratogens will cause developmental toxicity with every exposure, however.

Because every pregnancy has the risk of an abnormal outcome regardless of drug exposure, the objective of evaluating data on drug exposure during pregnancy is to ascertain whether a particular drug increases the risk of developmental toxicity in the fetus beyond the background rate. The following basic principles of teratogenicity should be applied when assessing the potential for teratogenicity of drugs.

CRITICAL STAGE OF EXPOSURE

After fertilization, the development of the embryo and fetus is divided into three main stages: pre-embryonic period, embryonic period, and fetal period.[28] In the first 2 weeks after fertilization or the pre-embryonic period (0–14 days), little is known about the effects of drugs on human development. Exposure to a teratogenic agent during this period usually produces an “all or none” effect on the ovum[31]: The ovum either dies from exposure to a lethal dose of a teratogenic drug or regenerates completely after exposure to a sublethal dose. Some animal studies have suggested, however, that exposure to some drugs during the preimplantation stage can halt growth and development before implantation.[36] Although the damage can be repaired, intrauterine growth may be retarded in the offspring.

During the embryonic period (14–56 days after fertilization), when organogenesis occurs, the embryo is most susceptible to the effects of teratogens or other chemicals.[25,31] Exposure during this sensitive period may produce major morphologic changes (Fig. 49-2). These stages of development differ significantly from other species, and knowledge of these stages is essential for the interpretation of the relationship between congenital malformations and drugs. For example, if a specific drug exposure occurs after the time of organ development, then a structural defect in that organ is less likely to be caused by that specific drug.

The fetal period (57 days to term) includes most of the stages of histogenesis and functional maturation, although the latter continues for some time after birth.[28] Minor structural changes are still possible during histogenesis, but anomalies are more likely to involve growth and functional aspects such as mental development and reproduction.

DOSE–RESPONSE CURVE

All teratogens follow a toxicologic dose–response curve.[25] All teratogens have a threshold dose below which adverse effects will not occur. The threshold dose is the dosage in which the incidence of structural malformations, rate of fetal death, growth restriction, and functional deficits does not exceed the background rate in the general population.[25] Conversely, developmental toxicity may occur when the fetus is exposed to doses above the maximum or threshold dose. There may be an increase in the severity and incidence of malformations when the fetus is exposed to increasingly higher dosages. For example, the risk for major congenital malformations, including NTD and minor anomalies, is increased statistically in patients taking valproic acid dosages greater than 1,000 mg/day during the first trimester.[37]

EXTRAPOLATION FROM ANIMAL STUDIES

In the absence of human trials, data derived from animal studies are used to assess the level of risk of developmental toxicity in humans. Most newly marketed drugs often have to rely on preclinical data to develop an estimation of teratogenic risk based on animal studies until human data become available.[38] The dose used in experimental animal data is expressed as multiples of the human dose using plasma or serum AUC or dose per unit based on body surface area.[39] The drug appears to have a low risk for teratogenicity if the toxic dose in animals (based on AUC or mg/m^2 comparison) is greater than 10 times the anticipated human dose.[40] Risk assessment using animal data is more complicated than just considering the dosage alone. Other major factors, including the effects of metabolism and active metabolites, species differentiation, route of administration, and type of defects, must be considered.[25]

GENETIC VARIABILITY

The most potent teratogenic agent will not produce malformations with every exposure.[25] The teratogenic potential of some drugs is influenced by the genotype of both the mother and fetus. Although the effects of known teratogens can be predictable in the general population, the possibility of individual assessment is difficult. The same dose of a teratogenic agent exposed at the same gestational window will produce variable outcomes in different people. Genetic variability can confer differences in cell sensitivities, placental transport, drug metabolism, enzyme composition, and receptor binding, which may affect how much active drug will reach fetal tissues.[41] One study showed an increased susceptibility to the teratogenic effect of phenytoin, most likely caused by elevated levels of oxidative metabolites (epoxides). These epoxides are normally eliminated from the systemic circulation by enzymes called microsomal epoxide hydrolase. Women who are homozygous for the recessive allele produce low levels of epoxide hydrolase, which may expose the fetus to higher levels of epoxides. These fetuses may be at a higher risk for fetal hydantoin syndrome.[42]

Table 49-1

Drugs with Suspected or Proven Teratogenic Effects in Humans

Alcohol	Growth restriction, mental retardation, mid-facial hypoplasia, renal and cardiac defects
Androgens (testosterone)	Masculinization of female fetus
Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers	Pulmonary hypoplasia, hypocalvaria, oligohydramnios, fetal kidney anuria, and neonatal renal failure
Antithyroid drugs	Fetal and neonatal goiter with iodine use; small risk of aplasia cutis with methimazole
β-Blockers	IUGR and decrease in placental weight in β-blockers with intrinsic sympathomimetic activity if used in second and third trimesters
Carbamazepine	Neural tube defects (NTDs), minor craniofacial defects, fingernail hypoplasia
Cigarette smoking	IUGR, functional and behavioral deficits
Cocaine	Bowel atresias; heart, limbs, face, and genitourinary tract malformations; microcephaly; cerebral infarctions; growth restriction
Corticosteroids (systemic)	Oral cleft lip and palates if used during organogenesis
Cyclophosphamide	Craniofacial, eye, and limb defects; IUGR; neurobehavioral deficits
Diethylstilbestrol	Vaginal carcinoma and other genitourinary defects
Lamotrigine	Oral cleft lip and cleft palate[33]
Lithium	Ebstein anomaly
Methotrexate	CNS and limb malformations
Misoprostol	Möbius sequence (high doses) and spontaneous abortions
Nonsteroidal anti-inflammatory drugs	Constriction of the ductus arteriosus, oral clefts, cardiac defects, and possible spontaneous abortion
Paroxetine	Cardiovascular defects[34]
Phenytoin	Fetal hydantoin syndrome, growth retardation, CNS deficits
Streptomycin and kanamycin	Hearing loss, eighth cranial damage; no ototoxicity reported with gentamicin, tobramycin, amikacin
Systemic retinoids (isotretinoin and etretinate)	CNS, craniofacial, cardiovascular defects
Tetracycline	Permanent discoloration of deciduous teeth
Thalidomide	Limb and skeletal shortening defects, internal organ defects
Topiramate	Cleft lip and cleft palate[35]
Trimethoprim	NTDs and cardiac defects
Vaccines (live)	Live attenuated vaccines can potentially cause fetal infection
Valproic acid	NTDs, developmental delay, and deficits
Vitamin A	Microtia, anotia, thymic aplasia, cardiovascular defects (high dose)
Warfarin	Fetal warfarin syndrome with nasal hypoplasia, stippled epiphyses, and skeletal and CNS defects

Teratogenic effects include the four major manifestations of abnormal fetal development which include growth alterations, functional deficits, structural malformations, and fetal death.

Only drugs that are teratogenic when used at clinically recommended doses are listed. List is not all-inclusive.

CNS, central nervous system; IUGR, intrauterine growth restriction.

PLACENTAL TRANSFER OF DRUGS

At one time, the placenta was thought to present a barrier to the passage of drugs and noxious chemicals to the fetus. It is now known, however, that most medications cross the placenta to the fetus and, in general, what the mother consumes also is consumed by the fetus. Although the placenta acts as a biologic membrane, it initially is composed of four layers effectively separating two distinct individuals.[41] These layers are (a) the endothelial lining of the fetal vessels, (b) the connective tissue in the core of the villus, (c) the cytotrophoblast layer, and (d) the covering syncytium. During gestation, the placenta's surface area increases while its thickness decreases from approximately 25 μm during the first trimester to 2 to 6 μm at term. Both processes tend to favor the transfer of chemicals to the fetus.

Drugs, nutrients, and other substances cross the placenta by five mechanisms: (a) simple diffusion (e.g., most drugs), (b) facilitated diffusion (e.g., glucose), (c) active transport (e.g., some vitamins, amino acids), (d) pinocytosis (e.g., immune antibodies), and (e) breaks between cells (e.g., erythrocytes).[41,42,39] The latter two mechanisms are of no practical importance in the transfer of drugs.

Several factors influence the rate of drug transfer across the placenta, including molecular weight, lipid solubility, ionization, protein binding, uterine and umbilical blood flow, and maternal diseases.[39] Drugs with molecular weights of less than 600 cross easily, whereas those of greater than 1,000 (e.g., heparin) cross with difficulty or not at all. Because most drugs have molecular weights of less than 600, it is safe to assume that most drugs reaching the mother's circulatory system also will reach the fetus. As with other biologic membranes, lipid-soluble substances are transferred rapidly, with the rate of entry primarily governed by the lipid solubility of the nonionized molecule. Conversely, those molecules that are ionized at physiologic pH (e.g., the cholinergic quaternary amines) cross slowly, whereas weak acids and bases with dissociation constant (pK_α) values between 4.3 and 8.5 are transferred rapidly to the fetus. The penetration of highly protein-bound drugs also is inhibited; only the free, unbound drugs cross the placenta.[41,38,39]

Uterine blood flow, a major factor in determining the rate of drug transfer, increases throughout gestation. Several variables can affect uterine blood flow and the rate of drug transfer, including maternal blood pressure (BP), cord compression, and drug therapy. Maternal hypotension reduces uterine blood flow and the rate at which substances are delivered to the membrane. Cord compression reduces the blood flow on the fetal side of the membrane. The use of drugs with α-adrenergic property (e.g., epinephrine) may constrict uterine vessels and thereby reduce blood flow.[27] Maternal diseases, such as pregnancy-induced hypertension, erythroblastosis, and diabetes, change the permeability of the placenta and may reduce or increase transfer.[36]

Food and Drug Administration (FDA) Risk Factors

In 1979, the US FDA introduced a system of rating pregnancy risks associated with pharmacologic agents. This system categorizes all drugs approved after 1983 into one of five pregnancy risk categories, A, B, C, D, and X. It establishes the level of risks to the fetus based on available animal and human data and recommends the degree of caution that should be undertaken with each drug.[38,40–42] This system had many limitations. Effective in June 2015, the FDA introduced pregnancy labeling and category system to include narrative text to provide more clinical management advice that includes consideration of both animal and human data (Fig. 49-1).[43] The structured narratives will include the following sections for each drug: a) pregnancy (including considerations during labor and delivery), b) lactation (includes nursing mother considerations), and c) females and males of reproductive potentionl.[43] For specific information on the FDA pregnancy labeling[43]: **http://www.fda.gov/drugs/developmentapprovalprocess/developmentresources/la**

The old FDA pregnancy classification structure states that levothyroxine is a pregnancy category A drug, but does not give any further specific information. The new FDA-structured narrative states "Levothyroxine (T_4) is compatible with all stages of pregnancy. Untreated or undertreated maternal hypothyroidism is associated with low birth weight secondary to medically indicated preterm delivery, preeclampsia or placental abruption, and with lower neuropsychological development of their offspring."[38] S.C. should be counseled that levothyroxine can safely be used during all trimesters of pregnancy including the period of organogenesis, which she is currently in at 8 weeks' gestation. She should not discontinue her levothyroxine. Thyroxine insufficiency has been shown to impair fetal and neonatal development. Levothyroxine therapy has not been observed to increase the risk of congenital malformations beyond the reported background risk of 3%.[38]

MANAGEMENT OF CONDITIONS IN PREGNANCY

Nausea and Vomiting

CASE 49-1, QUESTION 6: S.C. is now 10 weeks pregnant and complains of nausea throughout the day with occasional emesis occurring 2 to 3 times daily. She is able to tolerate at least two meals a day and oral liquids. She reports very little weight gain since she became pregnant. Her current weight is 72 kg. S.C. states that certain smells such as fish, eggs, and beans cause her to gag. How long is her nausea and vomiting likely to last?

According to American College of Obstetricians and Gynecology, nausea and vomiting during pregnancy (NVP) is a common condition occurring in approximately 70% to 85% of pregnancies, during weeks 5 to 12 of gestation.[44] For most women, NVP is a self-limiting condition that usually resolves after the first trimester with no long-term detrimental effect on the fetus.[47] About 91% of cases will resolve by 20 weeks of gestation.[45] The effects of NVP can have an impact on a woman's daily activities, work productivity, and quality of life. Studies estimate $130 million/year is spent on the hospitalization for severe NVP.[46] The cause of NVP is unknown, but is most likely multifactorial including hormonal, psychological, and neurologic factors. Changes in hormonal levels of estrogen, progesterone, and hCG have been implicated as a possible cause of NVP. Mild-to-moderate NVP has been associated with lower rates of miscarriage, preterm delivery, and stillbirth.[47]

NONPHARMACOLOGIC MANAGEMENT FOR NAUSEA AND VOMITING

CASE 49-1, QUESTION 7: What nonpharmacologic approaches should S.C. try for her nausea and vomiting?

Most mild forms of NVP can be managed with psychological support and lifestyle and dietary changes. Advising S.C. to eat smaller frequent meals consisting of a low-fat, bland, and dry diet (e.g., bananas, crackers, rice, toast), to avoid spicy and highly aromatic foods, and to take prenatal vitamins with iron at night may alleviate some of the symptoms. Meals high in protein are more likely to alleviate NVP than carbohydrate-laden or fatty meals. Rest and avoidance of the sensory stimuli occurring from foods, and lotions that may contribute to the effects of NVP can also be helpful.[47] Advise S.C. to avoid the foods (i.e., fish, beans, eggs, spaghetti sauce) that specifically trigger her gag reflex, which may induce emesis.

PHARMACOLOGIC MANAGEMENT FOR NAUSEA AND VOMITING

CASE 49-1, QUESTION 8: S.C. has tried crackers and avoiding the foods that trigger her gag reflex but does not respond to nonpharmacologic treatment of her nausea and vomiting. What pharmacologic agent would be appropriate for her?

Antiemetics are indicated for the treatment of moderate-to-severe nausea and vomiting that fails to respond to nonpharmacologic interventions or when the nausea or vomiting threatens the mother's metabolic or nutritional status (e.g., hyperemesis gravidarum). Traditionally, medications for NVP have been avoided during the first trimester because of fear of the possible teratogenic effects. Most antiemetic therapies (e.g., antihistamines, multivitamins, phenothiazines) can be taken during pregnancy safely. Table 49-23[8,46,48,50,51] shows the most common antiemetics used during pregnancy. The goal of antiemetic therapy is to choose an effective medication to improve a woman's quality of life by maintaining her nutrition and hydration needs, while ensuring fetal safety.

The FDA-recently-approved and prescription delayed-release formulation of 10 mg doxylamine with 10mg of pyridoxine (vitamin B_6) called Diclegis can be considered first-line therapy for the treatment of NVP. Several randomized, controlled trials have demonstrated its effectiveness in reducing NVP. Because of its safety and efficacy profile, doxylamine and pyridoxine are still considered a first-line therapy and are available in combination as prescription or separately as over-the-counter products.[48,52–54]

Other antihistamine H_1 receptor blockers (e.g., diphenhydramine, hydroxyzine, meclizine, dimenhydrinate) have been studied for NVP. The safety of antihistamines was supported in a meta-analysis including more than 200,000 first-trimester exposures, which did not find an increase in teratogenic risk.[49] Sedation is the main side effect that limits the use of this class of antiemetics.

Phenothiazines or metoclopramide is usually prescribed if antihistamines fail.[50,51] Phenothiazines (e.g., promethazine, prochlorperazine) are generally considered safe for both the mother and fetus if used occasionally in low doses. A recent randomized trial compared IV metoclopramide versus IV promethazine in the treatment of hyperemesis gravidarum and found both agents have similar efficacy. However, metoclopramide caused less drowsiness and dizziness.[50] Metoclopramide, a dopaminergic antagonist with prokinetic abilities, can control vomiting and gastric reflux associated with pregnancy. Oral metoclopramide can be added to an antihistamine (e.g., hydroxyzine) or a regimen of doxylamine and pyridoxine.[50,51] A large cohort study of 3,458 women exposed to metoclopramide in the first trimester failed to show an increase in congenital malformations. Metoclopramide issued a black box warning concerning the risk of rare incidences of tardive dyskinesia.[50,51] Risk of tardive dyskinesia increases with longer duration of treatment and total cumulative doses; thus, length of therapy beyond 12 weeks should be avoided.[50,51]

Due to the use of ondansetron, a 5-hydroxytryptamine type 3 antagonist during pregnancy has increased due to more experiences with its use. It is increasingly used for NVP and hyperemesis owing to ease of administration with oral disintegrating tablets and tolerability with minimal sedating side effects or poor fetal outcomes.[46,55] Methylprednisolone is an option for refractory cases; however, its use during the first trimester is associated with a small but significant risk of fetal oral clefts.

Alternative therapies (e.g., vitamin B_6, ginger root, acupuncture, acupressure) have improved NVP in a small number of patients.[38,45] S.C. may be started on doxylamine 10 mg and pyridoxine 10 mg 2 tablets by mouth at bedtime. S.C. may increase to 2 additional tablets in the afternoon if needed to a maximum of 4 tablets per day because of its safety and efficacy profile. Drug selection for S.C. mostly depends on the tolerability of adverse effects. If S.C. continues to have significant nausea and emesis on these antiemetics and fails to tolerate any oral liquids or solids, she should be advised to return to the clinic for evaluation and possibly be admitted for IV hydration and IV antiemetic therapy.

CASE 49-1, QUESTION 9: S.C. returns to the clinic a few weeks later at 12 weeks' gestation stating that she has lost about 4 kg in the past 3 weeks, has been unable to tolerate any liquids or medication for 2 weeks, and feels dehydrated and dizzy. S.C. is referred for admission to the hospital. What recommendations should be given to S.C. to help control her nausea and vomiting?

Severe NVP can persist in less than 1% of pregnancies, leading to a condition called hyperemesis gravidarum, which can lead to detrimental effects on the mother and fetus. Weight loss of more than 5% of prepregnancy weight, ketonuria, and electrolyte abnormalities are associated with this condition. Treatment of hyperemesis gravidarum often requires hospitalization for parental fluid administration, electrolyte replacement, vitamin supplementation, and antiemetic therapy.[47] Metabolic acidosis, ketosis, hypovolemia, electrolyte disturbances, and weight loss may ensue if patients are not treated.[47] Reductions in lower esophageal pressure, gastric peristalsis, and gastric emptying may worsen nausea and vomiting.

Table 49-2

Common Antiemetics Used for Nausea and Vomiting During Pregnancy (NVP)

Drug	Dose	Comments
Vitamin B_6 (pyridoxine)	10–25 mg PO TID	First-line therapy[45]; Documented safety in pregnancy
Vitamin B_6 (pyridoxine)–doxylamine combination	Pyridoxine 10–25 mg PO TID–QID; Doxylamine 12.5 mg PO TID–QID Doxylamine 10 mg/ Pyridoxine 10 mg PO QHS, Max 4 tablets/day	First-line therapy; Available OTC; Well-documented safety in pregnancy through large meta-analysis,[54] RX only
Antihistamines		
Diphenhydramine Meclizine Hydroxyzine Dimenhydrinate	25–50 mg PO every 8 hours 25 mg PO every 6 hours 25–50 mg PO every 4–6 hours 50–100 mg PO every 4–6 hours	First-line therapy; Antihistamines have not been shown to be teratogenic[49,50]
Phenothiazines		
Promethazine Prochlorperazine	12.5–25 mg PO, PR every 6 hours 5–10 mg PO every 6–8 hours	Second line of therapy; Available as suppositories; Also suppositories and buccal tablets; Usually add phenothiazine or metoclopramide to therapy if antihistamines fail[45,51]; Can cause EPS
Dopamine Antagonists		
Metoclopramide	10 mg PO every 6 hours	Usually add phenothiazine or metoclopramide to therapy if antihistamines fail[45,51]; Avoid treatment greater than 12 weeks’ duration, risk of tardive dyskinesia; Can cause EPS
Droperidol	1.25–2.5 mg IV/IM or Continuous infusion 1 mg/h for treatment of hyperemesis gravidarum[50]	Boxed warning regarding torsades de pointes, may need ECG during administration. Continuous infusion of droperidol requires concomitant diphenhydramine 50 mg IV every 6 hours

5-HT_3 Receptor Antagonists		
Ondansetron	4–8 mg IV/PO every 6–8 hours	Available as ODT tablets; Does not cause sedation; Studies suggest low risk in pregnancy[38,55]
Glucocorticoids		
Methylprednisolone	16 mg PO every 8 hours × 3 days, then taper over 2 weeks	For refractory cases, last line of therapy; Avoid use before 10th week of gestation, associated with oral cleft and palate[38,45]
Ginger extract	125–250 mg PO every 6 hours	Available OTC as food supplement

ECG, electrocardiogram; EPS, extrapyramidal symptoms; IM, intramuscular; IV, intravenous; ODT, oral disintegrating tablet; OTC, over-the-counter; PO, by mouth; QID, 4 times a day; TID, 3 times a day.

Source: Briggs G et al. Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk. 11th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017; Niebyl JR. Clinical practice. Nausea and vomiting in pregnancy. N Engl J Med. 2010;363:1544; McKeigue PM et al. Bendectin and birth defects: I. A meta-analysis of the epidemiologic studies. Teratology. 1994;50:27; Seto A et al. Pregnancy outcome following first trimester exposure to antihistamines: meta-analysis. Am J Perinatol. 1997;14:119.

In addition to ondansetron as mentioned above used for NVP, droperidol, an IV dopamine antagonist, has been used extensively for many years in the treatment of hyperemesis and the prevention and treatment of postoperative nausea and vomiting.[38] Although the FDA has mandated electrocardiographic monitoring for concern about the risk of prolonged QTc interval, large meta-analysis studies have failed to show an increased risk of arrhythmias when using droperidol at the low doses used for nausea and vomiting.[45] Limited experience with droperidol use in hyperemesis gravidarum has been documented in a small controlled trial.[52] Human and animal data suggest droperidol carries a low risk of teratogenicity to the fetus.[38,50,51]

S.C. should be hydrated with IV fluids with electrolyte replacement therapy and multivitamins including pyridoxine. If hydration with multivitamins does not quell her nausea, IV ondansetron 4 to 8 mg every 4 to 6 hours should be given. IV droperidol therapy should be considered if ondansetron does not work. She should also be evaluated for other causes of nausea and vomiting if her symptoms persist (e.g., gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer disease, pyelonephritis, and fatty liver of pregnancy).[47] Enteral nutrition may be needed in the treatment of hyperemesis gravidarum if S.C. cannot tolerate oral liquid and solid intake despite continuous IV antiemetics and hydration. Total parental nutrition should be reserved after multiple antiemetic regimens and enteral therapies have failed because of the substantial risks of catheter sepsis (25%) and thromboembolic clots.[45,46,50]

REFLUX ESOPHAGITIS

CASE 49-1, QUESTION 10: S.C. is now 30 weeks pregnant and no longer complains of nausea or vomiting. However, now she has heartburn that worsens when she lies down. What causes reflux esophagitis in pregnancy, and how should S.C. manage this problem?

Reflux esophagitis or heartburn is a normal occurrence in pregnancy affecting approximately two-thirds of women. The enlarging uterus increases intra-abdominal pressure, and estrogen and progesterone relax the esophageal sphincter. These two factors cause the reflux of stomach acid into the lower esophagus, producing symptoms of substernal burning worsened by eating, lying down, or bending over. Lifestyle and dietary modifications, such as eating smaller meals, avoiding late meals close to bedtime, and elevation of the head of the bed, should be tried first. Avoidance of salicylates, caffeine, alcohol, and nicotine are encouraged to reduce the symptoms of reflux and fetal exposure to these harmful substances.

If these modifications are not successful, S.C. should try a calcium carbonate antacid. Animal studies have not shown antacids to have teratogenic effects.[38] Sodium bicarbonate can cause metabolic alkalosis and fluid overload and should be avoided. Despite evidence of fetal toxicity with aluminum, available data suggest that usual doses of aluminum-containing medications are not harmful to the fetus of a pregnant woman with normal renal function. Sucralfate, which contains aluminum, appears to be safe in pregnancy. The American College of Gastroenterology has classified sucralfate as a medication with benefits that outweigh the risks when used in pregnant women.[38]

H_2-receptor antagonists can be used safely during pregnancy because most studies in animals and humans have not found fetal harm with cimetidine, ranitidine, famotidine, or nizatidine.[38] If H_2-receptor antagonists fail to control symptoms, proton-pump inhibitors (PPIs) should be used as the next treatment option. Recent studies have shown that PPI use during the first trimester and throughout pregnancy is not associated with a significant increase in the risk of congenital anomalies. These studies suggest that PPIs can be safely used at any gestational age.[56,57]

URINARY TRACT INFECTIONS

CASE 49-1, QUESTION 11: S.C. is now 31 weeks pregnant, and a routine urine dip was positive for leukocyte esterase and nitrates. Her urine was sent for urinalysis at her most recent prenatal visit and was positive for 10^5 colony-forming units (CFU) of Escherichia coli. She does not complain of any frequency and urgency when urinating and denies any fevers. Her temperature is currently 98.9°F. She denies any allergies to medications. What are the risks of having a urinary tract infection during pregnancy, and how should S.C. be treated?

Pathogenesis

Urinary tract infections are one of the most common complications of pregnancy owing to hormonal and mechanical changes that increase the likelihood of bacteriuria. During pregnancy, increases in progesterone cause relaxation of ureteral smooth muscle, promoting urinary stasis. The enlarging gravid uterus can also mechanically compress the ureters, which may lead to urinary retention. Approximately 90% of pregnant women may exhibit ureteral dilation or hydronephrosis, which can decrease bladder tone and ureteral tone. These physiologic changes along with increases in the GFR, urine alkalization, and glucosuria help to promote bacterial growth.

Asymptomatic Bacteriuria and Acute Cystitis

Urinary tract infections during pregnancy can present as either asymptomatic bacteriuria (ASB) or acute cystitis. ASB is defined as the presence of significant bacteria, greater than 10^5 CFU of bacteria, obtained by two consecutive clean-catch samples in the absence of any urinary symptoms.[58] In contrast, acute cystitis involves an infection of the bladder and manifests with signs and symptoms of frequency, urgency, dysuria, and hematuria without fever or evidence of systemic illness along with significant presence of bacteria of at least 10^5 CFU. Counts of less than 10^5 CFU with two or more organisms likely represent contamination and not true bacteriuria.

ASB is estimated to occur in 2.5% to 15% of pregnant women with about 80,000 to 400,000 cases occurring each year in the United States.[58,59] If ASBs are left untreated, they can lead to complications such as pyelonephritis, low-birth-weight infants, and premature delivery.[60] During pregnancy, treatment of ASB reduces the risk of developing pyelonephritis dramatically down from 20% to 35% to only 1% to 4%.[60] The US Preventive Services Task Force recommends screening for ASB with a urine culture for all pregnant women between 12 and 16 weeks of gestation or at the first prenatal visit if it occurs later.[61] The American College of Obstetrics and Gynecology (ACOG) further recommends repeating a urine culture during the third trimester.[62]

Risk factors for ASB during pregnancy include diabetes, sickle cell disease, immunosuppression, HIV or acquired immunodeficiency syndrome, urinary tract anatomic anomalies, and spinal cord injuries.[63] The primary sources of organisms that cause bacteriuria originate from existing vaginal and perineal flora and migrate up the urethra to cause ASB and cystitis; they include E. coli (most common pathogen isolated), Klebsiella pneumoniae, Proteus mirabilis, Enterobacter species, Enterococcus, Staphylococcus saprophyticus, and group B β-hemolytic Streptococcus.[63] Commonly used antibiotics include penicillins, cephalosporins, and nitrofurantoin. Antibiotic selection should be guided by antimicrobial susceptibility testing. For coverage of the most common organism, E. coli, oral nitrofurantoin or cephalexin is often used. E. coli resistance has been increasing to amoxicillin and trimethoprim-sulfamethoxazole.[63,64] The antibiotic chosen should produce adequate concentration in the urine, have a low resistance rate, and be safe to use during pregnancy. A 7-day regimen of antibiotics should be used whenever possible.[63,64] A recent WHO multicenter, randomized, noninferiority trial found a 7-day regimen with nitrofurantoin was more effective than a 1-day regimen in treating pregnant women with ASB, with bacteriologic cure rates of 86.2% and 75.7%, respectively.[64] Optimal antibiotics and duration of therapy have not been clearly identified and must be individualized for each patient based on cultures and sensitivity results.[60,63] For S.C., who likely has ASB, a 7-day course of nitrofurantoin is reasonable. At this gestation age of 31 weeks, nitrofurantoin can still be used safely. There is a small risk of hemolytic anemia in newborns when nitrofurantoin is used close to delivery.[38]

DIABETES MELLITUS

Diabetes mellitus is the most common maternal medical complications during pregnancy. Diabetes during pregnancy can be detected before or during pregnancy and can be separated into two groups: (a) pregestational diabetes, which includes women who have been diagnosed before pregnancy with either diabetes type 1 or diabetes type 2, or (b) gestational diabetes mellitus (GDM), defined as carbohydrate intolerance first detected during pregnancy.[65]

More prevalent than pregestational diabetes, GDM accounts for more than 90% of diabetes cases during pregnancy and affects approximately 6% to 7% of live births each year.[66] It is estimated that 50% of women with GDM will go on to develop type 2 diabetes 22 to 28 years postpregnancy.[67,68]

Pregestational diabetes accounts for the remaining 10% of cases. In the United States, more than 8 million women have pregestational diabetes, affecting about 1% of live births each year.[71] Most women with pregestational diabetes have type 2 diabetes characterized by peripheral insulin resistance and relative insulin deficiency.[69] The incidence of type 2 pregestational diabetes has been rapidly rising in the past decade, most likely because of the increasing prevalence of obesity. In contrast to type 2 diabetes, type 1 diabetes is characterized by complete insulin deficiency resulting from autoimmune destruction of pancreatic β-cells.[69] Less than 0.5% of all pregnancies in the United States are complicated by type 1 diabetes.[70]

Fluctuating glucose levels during the first trimester may be the first signs of pregnancy for women with pregestational diabetes owing to increased insulin resistance and reduced sensitivity to insulin action. Placental hormones (e.g., human placental lactogen, progesterone, prolactin, placental growth hormone, and cortisol) are thought to be responsible for the increase in insulin resistance during pregnancy. The ACOG classifies diabetes in pregnancy according to the White classification, modified to include gestational diabetes according to glycemic control. The White classification relies on age at onset, duration of diabetes, and presence of vascular complications for patient classification (Table 49-3).

Preexisting Diabetes Mellitus

FETAL AND INFANT RISKS

CASE 49-2

QUESTION 1: K.H., a 27-year-old, 60-kg woman known to have type 1 diabetes since age 12, has married recently and wishes to have children. She has been conscientious in her diabetes care and self-monitors her blood glucose concentrations two to three times a day (fasting and before meals). During the past month, her fasting blood glucose concentrations have ranged from 90 to 140 mg/dL. Today, her fasting blood glucose and glycosylated hemoglobin (Hgb A_{1c}) laboratory results are 134 mg/dL and 7.8%, respectively. Her BP is 145/94 mm Hg, renal function is normal, serum creatinine is 0.8 mg/dL, and she does not have proteinuria. K.H. reports tingling and pain in her toes. Her current medications include lisinopril 5 mg PO daily, insulin glargine (Lantus) 16 units subcutaneously (SC) every day at bedtime with an insulin lispro (Humalog) sliding-scale of 2 to 10 units before each meal. She reports eating only two meals a day and no snacks in between. How will diabetes affect the health of a child she would like to conceive?

Table 49-3

Modified White Classification of Diabetes During Pregnancy

Class of Diabetes	Age of Onset	Duration	Vascular Complications	Treatment of Choice During Pregnancy
Class A1	First diagnosed during pregnancy	During pregnancy	None	Diet, exercise
Class A2	First diagnosed during pregnancy	During pregnancy	None	Diet, exercise plus oral hypoglycemics or insulin
Class B	Older than 20 years	Less than 10 years	None	Insulin therapy
Class C	Between 10 and 19 years	More than 10 years, less than 19	None	Insulin therapy
Class D	Younger than 10 years	More than 20 years	Background retinopathy Hypertension Microalbuminuria	Insulin therapy
Class F	At any age	Any duration	Nephropathy Macroalbuminuria (>500 mg/day)	Insulin therapy

Class H	At any age	Any duration	Arteriosclerotic heart disease	Insulin therapy
Class R	At any age	Any duration	Proliferative retinopathy Vitreous hemorrhage	Insulin therapy
Class T	At any age	Any duration	Renal transplantation	Insulin therapy

Source: Cunningham FG et al. Diabetes. In: Gary Cunningham F et al, eds. Williams Obstetrics. 24th ed. New York, NY: McGraw-Hill; 2014; White P. Classification of obstetric diabetes. Am J Obstet Gynecol. 1978;130:228.

Perinatal mortality for infants of diabetic mothers has declined dramatically with strict maternal metabolic control, improved fetal surveillance, and neonatal intensive care.[71] Fetal and neonatal mortality rates are approximately 2% to 4%, and the risk of spontaneous abortion in patients with well-controlled type 1 diabetes is equal to that of women without diabetes.[72] The incidence of stillbirth is greatest after 36 weeks' gestation in women with poor glycemic control, fetal macrosomia (see subsequent discussion), maternal vascular disease, ketoacidosis, or preeclampsia.[65]

The leading cause of perinatal mortality is major congenital anomalies that occur in 9% to 14% of infants born to mothers with diabetes. The major malformations observed include NTDs and other anomalies involving the cardiac, renal, and GI systems, and rarely caudal regression syndrome.[66] Many congenital anomalies occur during organogenesis, before the seventh week of gestation, when women are often unaware that they are pregnant.[73] A direct correlation exists between higher Hgb A_{1c} levels and increased frequency of anomalies.[73] Women with elevated Hgb A_{1c} values during the time of conception have a significantly higher incidence of infants with abomalies compared with women with Hgb A_{1c} closer to the normal range of 4.0% to 5.6%.[74] The risk of fetal anomalies increases dramatically to approximately 20% to 25% when Hgb A_{1c} levels are near 10%.[73] Hgb A_{1c} levels greater than 12% are associated with the same risk of anomalies as infants exposed to known teratogens such as thalidomide, isotretinoin, or alcohol during organogenesis.

Macrosomia, defined as birth weight greater than 4 kg, is thought to be caused in part by fetal hyperglycemia and hyperinsulinemia.[65] Fetal hyperglycemia occurs when glucose crosses the placenta and subsequently stimulates fetal pancreatic β-cells to release excessive insulin. Hyperinsulinemia promotes excessive fetal growth in adipose tissue, causing disproportional fat concentration around the shoulders and chest and doubling the risks of trauma (e.g., shoulder dystocia) during vaginal delivery.

Infants of diabetic mothers also are at increased risk for prolonged hypoglycemia after delivery, respiratory distress syndrome (RDS), hypocalcemia, polycythemia, and hyperbilirubinemia during the neonatal period.[66]

K.H. should be informed that stringent preconception glycemic control is essential for preventing early pregnancy loss and congenital malformations in the infant.[71] Tight glucose control, especially in the months before pregnancy and early in the first trimester, will maximize her chance of having a healthy baby. She should be educated before pregnancy about healthy practices she can institute now to improve a successful pregnancy outcome.

MATERNAL RISKS

CASE 49-2, QUESTION 2: K.H. wants to know what health risks she might incur from becoming pregnant and what measures could minimize these risks?

A prepregnancy assessment, including a history and physical examination, is necessary to determine the risks of or contraindications to pregnancy for K.H. She should be evaluated for ischemic heart disease, neuropathies, or retinopathy, and her renal status must be assessed.[71] Pregnancy can exacerbate the vascular complications of diabetes. For instance, diabetic retinopathy can worsen if strict glycemic control is implemented quickly in pregnant women with proliferative retinopathy; progression to end-stage renal disease can occur in women with mild-to-moderate renal insufficiency (e.g., serum creatinine >1.5 mg/dL or proteinuria >3 g/24 hours).[66,69] The presence of gastroparesis should be noted because it will make controlling her glucose more difficult.[71]

Controlling K.H.'s diabetes before she becomes pregnant may benefit her hypertension and neuropathies and will minimize maternal and fetal problems. Good metabolic control of her diabetes can minimize progression of her diabetes.[73]

PRECONCEPTION MANAGEMENT

CASE 49-2, QUESTION 3: What prepregnancy interventions relative to her general health and diabetes should K.H. undertake before she attempts to become pregnant?

Pregestational care for K.H. should ideally begin 6 months before conception.[71] Recommendations for women with diabetes who want to conceive include suggesting birth control methods until stringent glycemic control can be achieved, consulting a dietitian to develop a patient-specific nutritional diet to attain healthy weight targets, and implementing a self-monitoring blood glucose regimen.[71] Good glycemic control (Hgb A_{1c} levels close to normal) should be achieved months before conception to minimize risks of major congenital anomalies. K.H.'s current regimen may not achieve euglycemia (see Chapter 53, Diabetes Mellitus). Her insulin therapy should be titrated to reduce her average blood glucose range from 90 to 120 mg/dL, targeting an Hgb A_{1c} of less than 6.5% without frequent episodes of hypoglycemia.[71,74] Additionally, K.H. should be started on prenatal vitamins containing at least 400 mcg of folic acid.

Her BP of 145/94 mm Hg is high and should be decreased to a diastolic BP of about 80 mm Hg to minimize risks for preeclampsia (see Case 49-5, Question 6) or exacerbation of her disorder. Many women with pregestational diabetes, such as K.H., are likely on an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker for hypertension treatment or for renal protective effects. Before pregnancy and during preconception planning, K.H. should be switched to another antihypertensive (e.g., methyldopa, labetalol, or calcium-channel blockers) such as methyldopa or labetalol because recent studies have observed possible increased rates of congenital cardiac malformation associated with the use of ACEIs in the first trimester.[75] Further confirmatory studies are needed to define the risk of using ACEIs during the first trimester. However, use of ACEIs is absolutely contraindicated during the second and third trimesters of pregnancy.[38,75]

TYPE 1 DIABETES TREATMENT IN PREGNANCY

CASE 49-2, QUESTION 4: After lowering her BP to 125/80 mm Hg with labetalol 200 mg PO twice daily and her Hgb A_{1c} to 7.3%, K.H. discontinues her oral contraceptive and returns to the clinic 5 months later and is noted to be about 4 weeks pregnant. How should her diabetes be managed at this time?

Goals of Therapy

The overall goals of treatment of K.H.'s diabetes are to reduce the maternal and fetal morbidity and mortality associated with diabetes. Treatment of diabetes (see Chapter 53, Diabetes Mellitus) should include dietary management, appropriate maternal weight gain, insulin therapy to normalize glycemic control, and exercise.

Dietary Management

The goals of dietary management for diabetes during pregnancy are directed at ensuring fetal growth and development, appropriate maternal weight gain, and normalizing maternal glucose concentrations. Patients often benefit from individualized diets developed by a dietitian. Neonatal macrosomia has been associated with high postprandial glucose levels; therefore, a reduction in postprandial hyperglycemia is an important goal.

Blood Glucose and Glycosylated Hemoglobin Monitoring

K.H. should begin to self-monitor her blood sugars more intensively at fasting, before meals, 1 hour postprandially, at bedtime, when she feels symptomatic hypoglycemia, and at 3:00 AM to rule out dawn phenomenon versus Somogyi effect.[76] The goal of therapy is to maintain fasting glucose levels less than 90 mg/dL, premeal values of less than 100 mg/dL, and 1-hour postprandial levels of 100 to 120 mg/dL.[66,69] Tight glycemic control without incidence of hypoglycemic episodes, targeting Hgb A_{1c} levels in the normal range, is the goal. Adjusting therapy based on postprandial glucose levels (as opposed to preprandial levels) can lower Hgb A_{1c} levels and decrease the risk of macrosomia, neonatal hypoglycemia, and cesarean delivery. Hgb A_{1c} levels can be drawn at each trimester to reveal the glycemic control during the previous 3 months.[68,69]

Insulin Therapy

Insulin analogs (e.g., lispro, aspart, glargine) are genetically engineered by recombinant DNA technology and usually differ by a few amino acids from human insulin. Concerns about insulin analog use during pregnancy include placental drug transfer and antibody formation.[77] The use of lispro (Humalog) and aspart (Novolog) insulin during pregnancy is supported by several studies that found minimal passage across the placenta, an absence of antibody formation, and no adverse maternal or fetal effects. Although the rapid onset of insulin lispro and aspart can increase adherence and patient satisfaction, it also may increase the incidence of hypoglycemia. Insulin glargine (Lantus), a long-acting insulin analog, allows for once-daily dosing and produces a peakless basal level of insulin. Only case reports have examined the safety and efficacy of insulin glargine during pregnancy.[38] Glargine is usually reserved for very brittle and sensitive insulin-dependent type 1 diabetes patients. Neutral protamine Hagedorn (NPH) insulin is usually used twice daily during pregnancy in lieu of insulin glargine as a basal insulin because it helps to control fasting blood sugars better than a peakless basal insulin. Newer insulin analogs such as insulin detemir (Levemir) and insulin glulisine (Apidra) have not yet been adequately studied during pregnancy and should not be used until further studies clarify their teratogenicity risk.[39]

Glycemic control is most difficult to establish during the first trimester of pregnancy because of the effect on blood sugars of maternal fluctuating hormones.[66,69] K.H.’s insulin regimen should be optimized by changing from insulin glargine to NPH insulin (with a 1:1 ratio) to help better control her fasting blood sugars and instituting a standard insulin lispro dosage before meals based on her carbohydrate intake. Sliding-scale insulin therapy is rarely used during pregnancy.[66,69] Insulin dosages commonly need to be monitored more strictly (every 2–4 days until glycemic control is achieved) during the first trimester and adjusted usually upward every 2 to 3 weeks during pregnancy.

TYPE 2 DIABETES TREATMENT IN PREGNANCY

CASE 49-3

QUESTION 1: V.W. is a 36-year-old G3, P0 with class B diabetes at 15 weeks’ gestation with a history of two spontaneous miscarriages occurring last year. She was diagnosed with diabetes 5 years ago during a routine physical examination. She is morbidly obese with a body mass index (BMI) of 49 kg/m^2, height of 5 feet

5 inches, and weight of 295 pounds. She recently found out that she was pregnant and has not had any prenatal care. Her current medications include metformin 1,000 mg PO twice daily and glipizide 5 mg PO daily. She states she has been noncompliant with checking her blood sugars, maintaining a diabetic diet, and taking her medication. Her last Hgb A_{1c}, which was 8.3%, was 2 months ago. Which medication and treatments should V.W. be started on?

Insulin Therapy

Insulin is the hypoglycemic agent of choice during pregnancy because it does not cross the placenta and has an established safety record for both mother and fetus. The goal with insulin therapy is to imitate the glucose levels of a healthy pregnant woman. Rapid glycemic control is of utmost importance during this critical period of organogenesis when vital organs are developing.[73]

Insulin requirements may vary, depending on the trimester. The first trimester is characterized by unstable diabetes, followed by a stable period.[65] During the first trimester, glucose and gluconeogenic substances in the blood are taken up by the fetus, which can lead to a decrease in maternal insulin requirements and increased episodes of hypoglycemia. On average, insulin dosages range from 0.7 to 0.8 units/kg/day in the first trimester.[66,69] If nausea and vomiting occurs during this time, glycemic control may be unstable and should be monitored closely. At about 24 weeks' gestation, insulin requirements begin to increase from 0.8 to 1 units/kg/day, and insulin doses may need to be adjusted every 5 to 10 days.[66,69] These needs continue to increase during the third trimester from 0.9 to 1.2 units/kg/day, which may be twice as much as the prepregnancy dose, in part because of the placental hormones (i.e., lactogen, prolactin, estrogen, and progesterone), which antagonize the action of insulin. Weight-based dosing may not accurately assess the insulin requirements in all pregnant women, especially in the obese population. Insulin regimens must be individualized for each patient, taking into consideration their educational level, compliance, and schedule constraints. Dosage adjustments must take into account the level of activity, meal plan, and other factors (e.g., steroid use, stress, infections) that may affect glucose control. Some women may be admitted into the hospital in the first trimester to (a) rapidly gain glucose control, (b) accurately assess their insulin requirements, and (c) institute an individualized insulin regimen under careful monitoring of blood sugars.[65]

An insulin regimen with three to four daily injections is most successful at maintaining adequate glucose control. Biosynthetic human insulin (e.g., regular and NPH insulin) is the usual treatment of choice in pregestational diabetes mellitus because of its chemical, biologic, and immunologic equivalency to pancreatic human insulin.[38] These insulins have the most established safety profile during pregnancy, but they require more stringent timing of meals during the day.[38]

V.W. should be switched from her oral hypoglycemic agents to insulin therapy with biosynthetic human regular insulin and NPH insulin. Metformin and glipizide should be discontinued. The total daily insulin dosage can be calculated by taking into account V.W.'s gestational age and actual body weight. Her total daily dose equals 0.8 units/kg × 134 kg, or 107 units daily. Using three injections per day, her dosage would be 47 units of NPH insulin plus 24 units of regular insulin SC 30 minutes before breakfast, 18 units of regular insulin SC 30 minutes before dinner, and 18 units SC of NPH insulin at bedtime. V.W.'s treatment plan needs to include dietary management; appropriate counseling on maternal weight gain during pregnancy given her morbid obesity; instructions on how to draw up, mix, and inject her insulin therapy to normalize glycemic control; and moderate exercise and walking 20 to 30 minutes after each meal. She should be taught to inject only in the subcutaneous abdomen area where insulin is best absorbed during pregnancy. V.W. should also be given a glucometer and taught how to self-monitor her blood sugars 4 times daily, at fasting and 1 hour postprandially (after the last bite of food from each meal) to target fasting blood glucose levels below 90 mg/dL and 1-hour postprandial levels less than 120 mg/dL.

Oral Hypoglycemic use in Type 2 Diabetes during Pregnancy

Although oral hypoglycemic agents are used commonly to treat type 2 diabetes in nonpregnant women, they are rarely used as

monotherapy during pregnancy. A switch to insulin therapy is recommended before conception, if possible, or at the time the pregnancy is confirmed because many patients have inadequate control with oral hypoglycemic agents.[66–69] If insulin is not started before conception, women should be strongly counseled to stay on oral hypoglycemics to adequately control blood glucose until insulin therapy can be implemented. Often, patients will discontinue oral hypoglycemics from fear of taking any medication in pregnancy, resulting in hyperglycemia during the critical period of organogenesis.

The ACOG recommends that the use of oral hypoglycemics for the treatment of type 2 diabetes during pregnancy be individualized until more safety and efficacy data become available.[66–71] There is limited experience with oral hypoglycemic use in type 2 diabetes during pregnancy. Metformin, a biguanide, has been used during pregnancy for hyperinsulinemic insulin resistance or in the treatment of infertility in women with polycystic ovarian syndrome (see Chapter 50, Disorders Related to the Menstrual Cycle). Women taking metformin should be switched to insulin therapy unless specific circumstances (e.g., high insulin requirements during the second or third trimester) warrant its use.[77.] Studies have shown the sulfonylureas are inferior to both insulin and metformin and increase risk for neonatal hypoglycemia.[74]

CASE 49-3, QUESTION 2: Should an oral hypoglycemic be added to V.W.'s insulin regimen?

V.W. should remain on insulin therapy with three injections daily. Her insulin regimen should be adjusted every 2 to 3 days until glycemic control is achieved and targeted blood glucose levels are reached without significant hypoglycemia episodes. Metformin should only be added if V.W.'s total daily insulin requirement exceeds 250 to 300 units. If metformin is added, insulin dosages should be decreased to at least half the amount in anticipation of increased insulin sensitivity.

Gestational Diabetes Mellitus

DIAGNOSTIC CRITERIA

CASE 49-4

QUESTION 1: J.B. is a 22-year-old Asian woman in the 24th week of her first pregnancy. She is 5 feet 2 inches, 75 kg (prepregnancy weight), and her BMI is 30 kg/m^2. At her regular prenatal visit, her obstetrician recommends an oral glucose screening test for GDM. Her Hgb A$_{1c}$ was 5.8%. Although her mother has diabetes, J.B. has had no glucosuria during pregnancy. Is J.B. at risk for GDM?

GDM is defined as carbohydrate intolerance that develops or is recognized during pregnancy regardless of severity, necessity for treatment, time of onset, or persistence after pregnancy.[78] GDM occurs in about 7% (range, 1%–14%), and the prevalence varies with the population and methods of detection.[78] Complications noted in the offspring of affected women include macrosomia, hypocalcemia, hypoglycemia, polycythemia, and jaundice. Women with GDM are more likely to experience pregnancy-induced hypertensive disorders or require a cesarean delivery. They also are at risk for type 2 diabetes later, and their children have an increased risk for obesity and diabetes later in life.

Risk factors for GDM include age older than 25 years, obesity (BMI ≥25 kg/m^2), family history of diabetes, previous delivery of an infant weighing more than 4 kg, a history of a stillbirth, a history of glucose intolerance, or current glycosuria.[78] African-Americans, Hispanic, Asian, Native American, and Pacific Islander women also are at increased risk for GDM.[66,78]

J.B. is at risk for GDM because she is Asian and obese, and she has a family history of diabetes. Her Hgb A$_{1c}$ at 26 weeks' gestation was normal and ruled her out for overt diabetes. J.B. should undergo the standard screening for gestational diabetes with a 50-g, 1-hour glucose challenge. It is not essential for J.B. to fast before this test. The diagnosis of GDM is important to the mother and the fetus because of the increased risks of fetal hyperinsulinemia and macrosomia.

GESTATIONAL DIABETES MELLITUS TREATMENT

CASE 49-4, QUESTION 2: J.B. is screened with a 50-g, 1-hour glucose challenge resulting at 161 mg/dL. Because her screening test was elevated, a diagnostic 3-hour oral glucose tolerance test (OGTT) was given to her the next day, which required her to be fasting. The results of the 3-hour OGTT showed a fasting plasma glucose of 96 mg/dL, a 1-hour glucose of 183 mg/dL, 2-hour glucose of 140 mg/dL, and 3-hour glucose of 126 mg/dL. These results confirm that J.B. has GDM. How should she be managed?

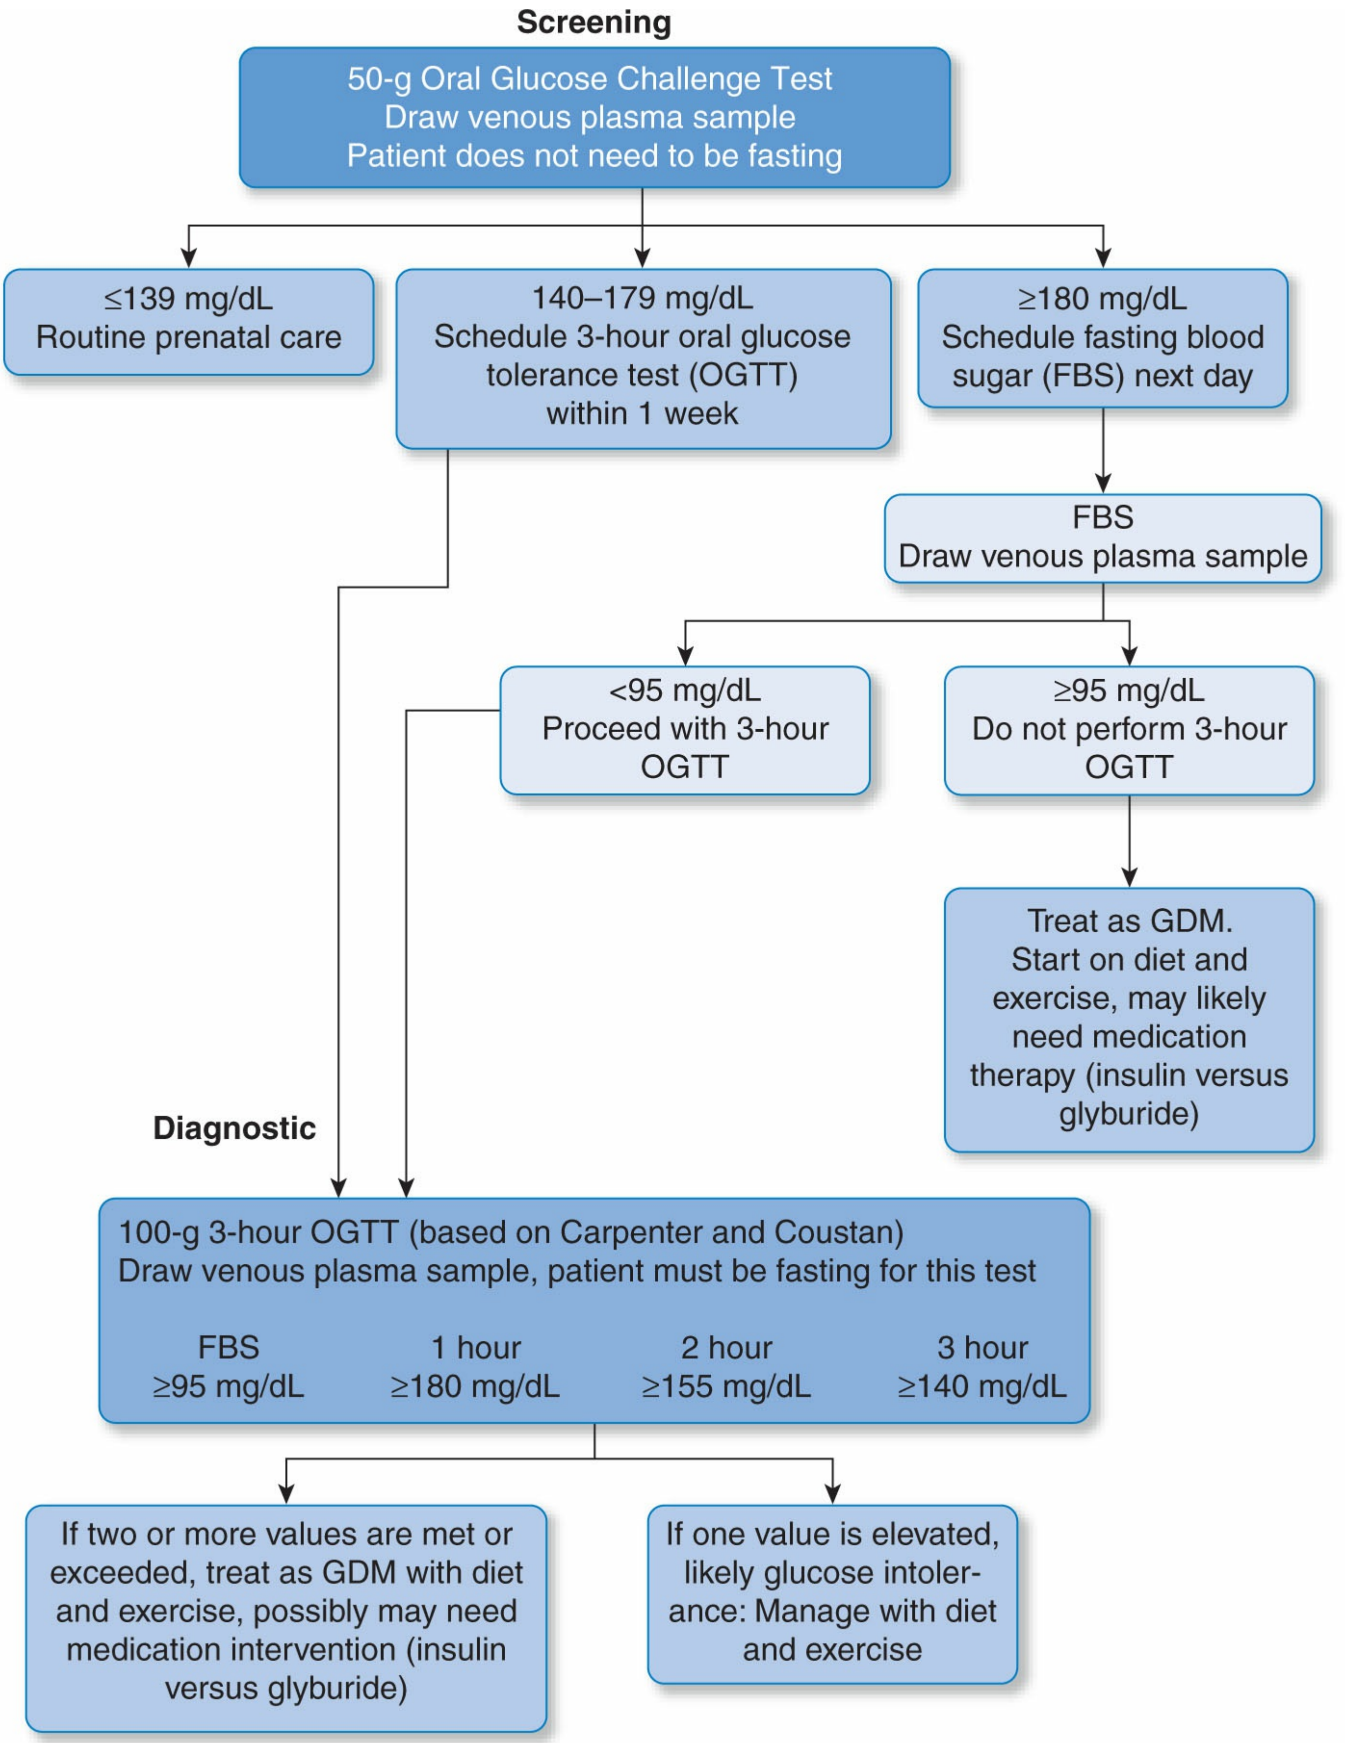
J.B. requires extensive education about a gestational diabetes diet, use of a glucometer, the signs and symptoms of hyperglycemia and hypoglycemia, and treatment of low blood glucose. She should start to monitor her blood glucose 4 times daily, at fasting and 1 hour after the end of each meal. She should return to the clinic in 1 week for an assessment of her blood sugars to evaluate the need for medication therapy (insulin versus glyburide treatment).

It is suggested that 60% to 85% of patients with GDM can control their glucose with dietary modifications and regular exercise; however, management with medications (insulin vs. oral hypoglycemics) should be initiated if dietary management fails to maintain fasting plasma blood glucose concentrations at 95 mg/dL or less or to achieve a 1-hour postprandial plasma concentration of less than 140 mg/dL.[74] Figure 49-3 outlines recommendations for screening and diagnosis of gestational diabetes.

CASE 49-4, QUESTION 3: J.B. returns to clinic at 30 weeks' gestation with glucometer and logbook for a blood glucose assessment. She has been compliant with her diabetic diet and blood sugar monitoring for the past 4 weeks. She has been able to control her blood sugars with diet and moderate walking after meals. However, she has noticed that her fasting blood glucose has risen in the past week to an average of 98 mg/dL and her dinner postprandial values are averaging 139 mg/dL. How should J.B. be managed at this time?

Treatment of GDM with insulin therapy is implemented similar to the treatment for pregestational diabetes. An optimal insulin regimen for GDM has not been determined. Similar dosing with a weight-based, split-mixed multidose regimen is used. The insulin regimen must be tailored specifically to the needs of the woman to successfully achieve target blood glucose levels.

More recently, the Metformin in Gestational Diabetes trial examined whether metformin treatment could provide equivalent outcomes to insulin treatment. Women with GDM at 20 to 33 weeks' gestation were randomly assigned to open-label treatment with metformin (titrated up to 2,500 mg with the option to add supplemental insulin if glycemic control was not achieved) or to insulin treatment alone.[79] The two groups achieved similar primary outcomes (composite score of neonatal morbidities), but 46% of the group allocated to metformin required supplemental insulin therapy. Those requiring supplemental insulin were more obese and had higher elevations of glycemic values at presentation. The results indicate that metformin can be used during pregnancy for GDM, but will less likely be successful as monotherapy in women with higher glucose levels.[79] Metformin is usually reserved for patients with high insulin requirements (>300 units daily) in the second and third trimesters.[38] More randomized trials are needed to further determine and to better understand the role of oral hypoglycemic agents in pregnancy.



Screening
50-g Oral Glucose Challenge Test
Draw venous plasma sample
Patient does not need to be fasting
≤139 mg/dL
Routine prenatal care
140–179 mg/dL
Schedule 3-hour oral glucose tolerance test (OGTT) within 1 week
≥180 mg/dL
Schedule fasting blood sugar (FBS) next day
FBS
Draw venous plasma sample
<95 mg/dL
Proceed with 3-hour OGTT
≥95 mg/dL
Do not perform 3-hour OGTT
Treat as GDM. Start on diet and exercise, may likely need medication therapy (insulin versus glyburide)
Diagnostic
100-g 3-hour OGTT (based on Carpenter and Coustan)
Draw venous plasma sample, patient must be fasting for this test
FBS
≥95 mg/dL
1 hour
≥180 mg/dL
2 hour
≥155 mg/dL
3 hour
≥140 mg/dL
If two or more values are met or exceeded, treat as GDM with diet and exercise, possibly may need medication intervention (insulin versus glyburide)
If one value is elevated, likely glucose intolerance: Manage with diet and exercise

Figure 49-3 Recommendations for screening and diagnosis of gestational diabetes. FBG, fasting blood glucose; GDM, gestational diabetes mellitus; OGTT, oral glucose tolerance test. (Adapted with permission from Screening and diagnosis of gestational diabetes mellitus. Committee Opinion No. 504. American College of Obstetricians and Gynecologists. Obstet Gynecol. 2011;118: 751–753.)

Other oral hypoglycemics, such as the sulfonylureas, have inferior data and increase risk of adverse effects.[74]

J.B. is a good candidate for insulin therapy because she is greater than 30 weeks' gestation and has a fasting blood sugar level less than 110 mg/dL. Doses should be increased or decreased to achieve glycemic control.

RISK OF DEVELOPING DIABETES MELLITUS

CASE 49-4, QUESTION 4: Why is J.B. at risk for developing diabetes mellitus after delivery?

Glucose tolerance normalizes after delivery for most women. Women with GDM, however, have a 15% to 50% chance of developing nongestational diabetes within 5 to 16 years.[72] The highest risk is in women who are obese or were diagnosed before 24 weeks' gestation or who had marked hyperglycemia during or soon after pregnancy. The risk of developing GDM in a future pregnancy is estimated to be 50%[66,78]

J.B. should try to minimize the potential for development of insulin resistance by exercising and maintaining a normal weight. She should also have her glucose checked with a 2-hour OGTT at her postpartum appointment 6 weeks after delivery and then at least every 1 to 3 years with screening of either fasting blood sugar or HgbA1c. In addition, J.B. should be instructed about the importance of using an effective birth control method to prevent unplanned pregnancies. She also needs to schedule regular appointments with her primary-care clinician.

HYPERTENSION AND PREECLAMPSIA

Chronic Hypertension

CLINICAL PRESENTATION

CASE 49-5

QUESTION 1: T.D., a 37-year-old G1, P0, obese black woman was diagnosed with stage 1 hypertension several months before her pregnancy (BP, 135–145 mm Hg systolic and 90 to 95 mm Hg diastolic). She had no cardiovascular risk factors (i.e., smoking, diabetes mellitus, dyslipidemias) and was prescribed a trial of lifestyle modification (i.e., weight loss and exercise). When she initiated prenatal care at 16 weeks' gestation, her BP ranged from 130 to 135 mm Hg systolic pressure and 82 to 85 mm Hg diastolic pressure. Her BP today at 28 weeks is 142/90 mm Hg. Her serum chemistry values are creatinine (SCr), 0.6 mg/dL, and UA, 4 mg/dL. A random urinalysis did not demonstrate proteinuria. Ultrasound confirms an adequately growing fetus at 28 weeks' gestation. What type of hypertension does T.D. have? What is the likelihood T.D. has preeclampsia?

Hypertensive disease occurs in 5% to 8% of all pregnancies and is a major cause of maternal and perinatal morbidity and mortality.[80] From 15% to 24% of maternal deaths in developed countries are attributed to hypertensive disorders in pregnancy.[81,82] Hypertension in pregnancy is defined as a systolic BP of at least 140 mm Hg or a diastolic BP of at least 90 mm Hg on two separate occasions at least 6 hours apart.

Women with pregnancy-associated hypertension can be grouped into the following categories: chronic hypertension, preeclampsia–eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.[80] After delivery, gestational hypertension is ultimately delineated as either (a) transient hypertension of pregnancy if preeclampsia is absent during delivery and BP normalizes by 12 weeks postpartum or (b) chronic hypertension if BP remains elevated.[80]

Chronic hypertension is defined as hypertension diagnosed before conception or before the 20th week of gestation, or hypertension persisting beyond 12 weeks postpartum.[80] Hypertension noted after the 20th week of gestation might be difficult to classify, particularly if a woman has had inadequate prenatal care without appropriate BP monitoring.

Women with chronic hypertension, similar to T.D., commonly have a normal BP during the first half of pregnancy because of the physiologic decline of BP during the second trimester.[83] BP usually returns to the prepregnancy level by the third trimester. T.D.’s diastolic pressure decreased from the prepregnancy levels of 90 to 95 mm Hg to 86 to 90 mm Hg during the second trimester. It is normal for T.D.’s BP to increase during the third trimester. These changes in BP make it difficult to differentiate chronic hypertension from preeclampsia during the second half of pregnancy in women with late prenatal care or inadequate BP monitoring. It is also difficult to diagnose preeclampsia superimposed on existing hypertension using BP measurements alone. A sharp increase in T.D.’s pressure of more than 30 mm Hg systolic or more than 15 mm Hg diastolic could be consistent with preeclampsia. Without coexisting proteinuria (≥0.3 g/24 hours or ≥1+ in a random urine sample) or evidence of renal dysfunction, a diagnosis of preeclampsia would be a reach.[83] T.D. has no proteinuria, and a normal SCr and serum UA. T.D has chronic hypertension, but it is unlikely that T.D. has preeclampsia at this time.

RISK FACTORS FOR PREECLAMPSIA

CASE 49-5, QUESTION 2: What risk factors does T.D. have for developing preeclampsia?

Preeclampsia is a pregnancy-specific condition usually occurring after 20 weeks’ gestation and consisting of hypertension with proteinuria.[83] Preeclampsia can affect multiple organ systems (e.g., kidney, liver, hematologic, CNS). The signs and symptoms are often unpredictable and can be mistaken for other disorders. Because edema is so common in normal pregnancy and is not specific, it is no longer used as a criterion for the diagnosis of preeclampsia. Preeclampsia is a consequence of progressive placental and maternal endothelial cell dysfunction, increased platelet aggregation, and loss of arterial vasoregulation. A variant of preeclampsia is Hemolysis, elevate Liver enzymes, Low Platelet count (HELLP) syndrome, which consists of hemolysis (H), elevated liver (EL) enzymes, and low platelet (LP) count. HELLP can also be life–threatening and may not always present with proteinuria and increases in BP.[84]

When women with preeclampsia exhibit seizures, the term eclampsia is used. Women with preeclampsia may unpredictably progress rapidly from mild-to-severe preeclampsia and to eclampsia within days or even hours. Eclampsia is a potentially preventable complication of preeclampsia. About 20% of women who experience eclampsia have a diastolic BP less than 90 mm Hg or no proteinuria.[85]

The term gestational hypertension is used when BP is increased during pregnancy or is increased in the first 24 hours postpartum in a woman without signs or symptoms of preeclampsia and without preexisting hypertension.[80] Women with gestational hypertension are at high risk of recurrence during subsequent pregnancies.

Preeclampsia occurs most commonly during the first pregnancy (two-thirds of cases). Obesity and increasing maternal age are risk factors.[86] Chronic diseases that increase the risk for preeclampsia include diabetes mellitus or insulin resistance and renal disease. Pregnancy-associated risk factors include multifetal gestations, urinary tract infection, certain fetal chromosomal anomalies, and hydatidiform moles. A family history of a sister or mother with preeclampsia significantly increases the risk of developing preeclampsia. Women with previous preeclampsia are at high risk for recurrence in subsequent pregnancies, particularly if it developed before 30 weeks' gestation.[86,87] In addition to her age and obesity, chronic hypertension is the most significant aspect of T.D.'s medical history, which confers a 25% risk of developing superimposed preeclampsia.[87]

Monitoring

CASE 49-5, QUESTION 3: What subjective and objective data should be monitored in T.D. for the development of preeclampsia?

T.D. should have her BP monitored frequently. If protein is detected in a random urinalysis, then a 24-hour urine collection for protein and creatinine can be repeated to determine accurately the degree of proteinuria and severity of disease.[80] Periodic ultrasounds should be obtained to assess fetal growth because IUGR is common in pregnant women with chronic hypertension. T.D. should be taught to recognize and immediately report all signs and symptoms of preeclampsia, such as nondependent edema (i.e., swelling of face or hands), headaches, and visual disturbances. The latter two are signs of severe preeclampsia and may indicate impending eclampsia. Upper abdominal pain also can be a sign of severe preeclampsia, indicating hepatic subcapsular hemorrhage.[86] Because T.D. has chronic hypertension, worsening of hypertension alone may not be a reliable sign of superimposed preeclampsia. Proteinuria is the best indicator of superimposed preeclampsia in a pregnant woman with chronic hypertension and no renal disease.[85]

Antihypertensive Drug Therapy

CASE 49-5, QUESTION 4: Should T.D.'s chronic hypertension be treated with antihypertensive drugs to prevent preeclampsia?

The goal of antihypertensive therapy for women with chronic hypertension during pregnancy is to minimize the risks to the mother of an elevated BP without compromising placental perfusion.[84] The value of treating pregnant women with chronic antihypertension drugs remains an area of ongoing debate. A sustained diastolic BP of more than 100 mm Hg may cause maternal vascular damage, especially if the diastolic pressure is more than 105 to 110 mm Hg.[86] Morbidity is unlikely with a diastolic BP of less than 100 mm Hg. Therefore, many clinicians recommend treatment with antihypertensive drugs to lower diastolic pressures of more than 100 to 110 mm Hg.[80] Treatment of a diastolic BP of less than 100 mm Hg should be reserved for women with chronic hypertension and target organ damage (e.g., left-ventricular hypertrophy) or underlying renal disease because antihypertensive drugs can decrease placental blood flow, which might increase fetal growth restriction.[88,89] Treatment of mild-to-moderate hypertension is associated with a decrease in the risk of developing severe hypertension by approximately 50%, but the overall risk of developing preeclampsia is unchanged.[90] Furthermore, there is no evidence of a reduction in the risk of stillbirth, fetal growth restriction, or preterm birth if women with chronic hypertension with systolic BP of 140 to 169 mm Hg or diastolic BP of 90 to 109 mm Hg are given antihypertensive therapy.[90] Moreover, women treated with antihypertensive therapy were more likely to experience adverse drug effects compared with those who received placebo or were untreated. Antihypertensive therapy, however, is required to reduce the risk of cardiovascular morbidity such as heart or renal failure and acute risk of stroke in pregnant women with severe hypertension (diastolic >110 mm Hg).

T.D. has normal renal function and her BP is less than 100 mm Hg; she does not need antihypertensive drug treatment at this time. If T.D. had been on drug therapy before conception, some experts would have her continue during the pregnancy.[80,85,88] In such cases, however, the doses of the antihypertensive agents often need to be lowered or discontinued altogether to prevent hypotension because the maternal BP naturally decreases during the second trimester. Perinatal outcomes in women with untreated chronic hypertension who do not progress to preeclampsia are similar to those of the general obstetric population.[85] Although chronic hypertension is a major risk factor for preeclampsia, treating T.D.'s uncomplicated mild chronic hypertension is unlikely to prevent the development of preeclampsia.

Methyldopa

CASE 49-5, QUESTION 5: When T.D. returns to the clinic 2 weeks later at 30 weeks' gestation, her BP ranged from 160 to 165 mm Hg systolic pressure and 85 to 92 mm Hg diastolic pressure. Which medication should T.D. be started on?

Methyldopa, a centrally acting α-agonist that decreases sympathetic outflow to decrease BP, is the most commonly used antihypertensive agent for chronic treatment of hypertension in pregnancy in the United States. The usual starting dose of 750 to 1,000 mg/day, to be administered in three to four daily divided doses, can be increased to 2 or 3 g/day if needed. Higher doses may be needed to control BP in pregnancy.[91]

Methyldopa, classified as category B for fetal risk, has the longest and best safety record of all antihypertensive agents during pregnancy. Despite its common use, few adverse effects have been reported in neonates exposed to methyldopa in utero. In addition, no congenital anomalies are associated with methyldopa.[38]

Dizziness and sedation, accompanied by a loss of energy, are among the most common adverse effects reported by pregnant women.[91] Generally, these adverse effects occur early in therapy and tend to subside, but may recur with an increased dosage. Problems with postural hypotension usually do not occur in pregnant women.[91] Patients should be monitored for methyldopa-induced liver damage.[87] Other drugs used to treat hypertension in pregnancy include labetalol and calcium-channel blockers. A review of drug therapies for the treatment of chronic hypertension in pregnancy is listed in Table 49-4.[92–97]

T.D. should be started on methyldopa 500 mg PO 3 times daily. If T.D. cannot tolerate the side effects, she can be switched to labetalol 200 mg PO twice daily. The only antihypertensive drugs absolutely contraindicated during pregnancy are ACEI and angiotensin II receptor blockers because of the association with fetal and newborn morbidity and mortality.[88]

Mild Preeclampsia

CASE 49-5, QUESTION 6: T.D. returns to her obstetrician 1 week later at 31 weeks' gestation complaining of mild hand and leg edema. She has 1+ proteinuria by dipstick, and her BP is 155/102 mm Hg. An ultrasound demonstrates fetal growth restriction. Laboratory results are as follows:

SCr, 0.9 mg/dL
Serum UA, 6.0 mg/dL
Aspartate aminotransferase (AST), 25 units/L
Alanine aminotransferase (ALT), 16 units/L
Platelets, 230,000/μL

She is currently on labetalol 200 mg PO twice daily and has been compliant with her medications. What signs and laboratory evidence are consistent with preeclampsia in T.D.? Does she have mild or severe preeclampsia?

ETIOLOGY AND PATHOGENESIS

The causes of preeclampsia currently remain unknown. Although the pathogenesis begins early in pregnancy, the disease is not clinically evident until the latter half of the pregnancy and persists until the fetus is delivered.[98] Incomplete physiologic placental vascular bed changes and endothelial cell dysfunction are integral to the pathogenesis of preeclampsia.

Placental Ischemia

Early in a normal pregnancy, the trophoblastic migration and invasion of the uterine spiral arteries result in physiologic changes within the placental vascular bed that facilitate maximal intervillous blood flow. The physiologic changes within these spiral arteries are responsible for creating a fixed low-resistance arteriolar circuit, which increases blood supply to the growing fetus. In preeclampsia, these physiologic changes do not occur completely, resulting in decreased perfusion and, consequently, placental ischemia.[98,99]

Endothelial Damage

An intact vascular endothelium assists in preserving the integrity of vasculature, mediating immune and inflammatory responses, preventing intravascular coagulation, and modulating the contractility of the underlying smooth muscle cells.[99]

In normal pregnancy, prostacyclin is increased 8 to 10 times, creating an increased ratio of prostacyclin to thromboxane A_2.[98] The biologic dominance of prostacyclin along with nitric oxide plays an important role in maintaining vasodilation throughout pregnancy. Prostacyclin may be responsible for vascular refractoriness to angiotensin II in normal pregnancy. In preeclampsia, the ratio of prostacyclin to thromboxane A_2 is reversed. Thromboxane A_2 is biologically dominant during preeclampsia, leading to increased vascular sensitivity to angiotensin II and norepinephrine.[98] The increased release of thromboxane A_2 is believed to be caused by endothelial cell dysfunction. The end result is vasospasm, which further increases endothelial cell dysfunction and increases BP.[98] Reduced activity of nitric oxide synthase and decreased nitric oxide-dependent or nitric oxide-independent endothelium-derived relaxing factor are believed to increase the vasoconstrictive potential of pressures such as angiotensin II.[80]

Table 49-4

Drugs for Treatment of Chronic Hypertension in Pregnancy and Lactation

Drug	Dose	Comments
Methyldopa	750–1,000 mg/day start twice a day, increase up to 2–3 g/day, divided in 3–4 doses if needed[99]	Longest safety record in pregnancy. Considered a first-line drug.[88] Dizziness, sedation, and lack of energy are common symptoms, which tend to resolve. Can cause liver toxicity. Low breast milk concentrations, so considered safe in breast-feeding
Labetalol	200–400 mg/day start, increase to up to 2,400 mg/d, divided in 2 or sometimes three doses	Combined α- and β-receptor antagonist properties. Considered a first-line drug.[88] Increasingly preferred to methyldopa owing to fewer side effects. Neonatal effects could include bradycardia and hypotension. Low concentration in breast milk and generally considered safe in breast-feeding[92]
Other β-blockers	Various	Atenolol in particular associated with decreased placental weight and IUGR.[94,95] IUGR thought to be related to β-blocker-induced increased vascular resistance in mother and fetus. Atenolol, acebutolol, metoprolol, nadolol, and sotalol can have high milk-to-plasma ratios and accumulate in breast milk, creating potential risk for neonatal blockade.[96,97] Propanolol found in only small amounts in breast milk and generally considered safe, but infants should be monitored for hypotension, bradycardia, and blood glucose changes
Nifedipine, long-acting	30 mg/day start, increase to up to 120 mg/day, once daily	Limited pregnancy data on nifedipine or other calcium-channel blockers such as verapamil, diltiazem, and amlodipine. Concentrations of nifedipine in breast milk are low and considered compatible with breast-feeding[107,108]
Diuretics	Various	Not first-line agents, although probably safe.[88] Concern regarding potential interference with normal blood volume expansion in pregnancy. Avoid if preeclampsia or IUGR already present. Concentration low in breast milk, but may decrease milk production
ACEI or ARB	Contraindicated	Contraindicated in pregnancy in all trimesters. Fetal renal failure when used after first trimester, resulting in oligohydramnios, limb contractures, pulmonary hypoplasia, skull hypoplasia, and irreversible neonatal renal failure.[38] Increased risk major birth defects with first-trimester ACEI exposure.[75] Minimal amounts of captopril and enalapril in breast milk and both considered compatible with breast-feeding.[229] Minimal amounts of benazepril in breast milk

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; IUGR, intrauterine growth restriction.

Endothelial cell dysfunction in pregnancy is thought to be caused by oxidative stress. Intermittent hypoxic and reperfusion injury that occurs as a consequence of decreased placental perfusion may increase oxidative stress.[98,99] Endothelial damage eventually leads to disruption of the vascular lining, which causes leaking capillary membranes, allowing fluid to leak into the interstitium.[99] In severe preeclampsia, this results in hypovolemia, hemoconcentration, and consequently an increase in hematocrit. The loss of plasma volume, vasospasm, and microthrombi decrease perfusion of the kidney, CNS, liver, and other organs. The loss of intravascular proteins in the urine secondary to renal damage, and through damaged epithelia, decreases plasma oncotic pressure and leads to a rapid onset of nondependent edema. The imbalance of endogenous procoagulants and anticoagulants produces platelet consumption and results in thrombocytopenia and coagulation defects.[99]

T.D.'s diastolic BP is now higher than it was before her pregnancy and has increased by 12 mm Hg in the last 3 weeks. Although an increase in BP by itself is not diagnostic of preeclampsia, the new finding of proteinuria confirms the diagnosis. Other evidence for preeclampsia includes the elevated serum UA concentration, which is a sensitive marker for preeclampsia, and elevated SCr.[86] T.D. denies headaches, visual disturbances, and abdominal pain, which are symptoms of severe preeclampsia. The transaminases and platelet count are normal; therefore, she does not have HELLP syndrome at this time. T.D.'s clinical presentation is consistent with mild preeclampsia; however, a 24-hour urine collection should be obtained to measure protein excretion, quantify the urine output, and further rule out severe preeclampsia.

TREATMENT OF PREECLAMPSIA

General Principles

CASE 49-5, QUESTION 7: T.D. is admitted to the hospital. The 24-hour urine protein is 500 mg/24 hours. Although fetal growth is restricted, all other fetal testing is reassuring. After 24 hours, her BP decreased to 140/95 mm Hg. Her platelet counts remained stable and greater than 200/μL, and transaminases were normal. No other signs and symptoms of preeclampsia were noted. How should T.D.'s mild preeclampsia be managed?

The delivery of the fetus is the only cure for preeclampsia and would be the best treatment option for T.D. if she were at more than 37 weeks' gestation. T.D. has mild disease, however, and is not close to term. Her delivery should be postponed

---

because premature delivery increases neonatal morbidity and mortality. T.D.'s fetus is somewhat growth restricted, which is common in women with chronic hypertension, with or without superimposed preeclampsia. If T.D.'s fetus is severely growth restricted or if subsequent fetal biophysical testing is abnormal, premature delivery would be indicated.[80] Because neither of these is evident in the present circumstances, T.D. should continue her pregnancy under very close medical supervision. It has been suggested that continued hospitalization is appropriate for women with preterm onset of mild preeclampsia, such as T.D.[80] This would allow for rapid intervention in case of rapid progression of disease or associated complications. Probably, a role exists for outpatient monitoring of some select women with very frequent maternal and fetal monitoring, and rehospitalization for worsening disease.[80]

T.D. is also a candidate for administration of glucocorticoids for fetal lung maturation (see Case 49-7, Question 7). Bed rest in the lateral decubitus position is usually suggested and may help reduce BP and promote diuresis by decreasing vasoconstriction and improving renal and uteroplacental perfusion.

T.D. should have her BP measured regularly each day. Liver transaminases, platelets, and creatinine should be measured periodically and whenever her clinical status changes. She also should be assessed for symptoms of severe preeclampsia (e.g., headaches, visual disturbances, epigastric or right upper-quadrant pain). Fetal surveillance is indicated.[80] One approach is to perform a modified biophysical profile, a test performed to ensure fetal well-being using ultrasonography measuring fetal breathing, tone, movement, and amniotic fluid volume with an assessment in fetal heart rate, twice a week and whenever maternal clinical status changes, and an ultrasound for fetal growth every 3 to 4 weeks.

Severe Preeclampsia

CLINICAL PRESENTATION

CASE 49-5, QUESTION 8: T.D.'s BP for about 2 weeks ranged from 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic with bed rest. Her proteinuria remained stable at 1+ to 2+ by dipstick. During the past 2 days T.D.'s BP started to increase again, and today her BP is 160/112 mm Hg and her urine dipstick is 3+. She complains of headaches, dizziness, and visual disturbances and has significant edema in her face, hands, legs, and ankles. T.D. is transferred to the Labor and Delivery Unit for delivery. Pertinent laboratory results are as follows:

SCr, 1.3 mg/dL
UA, 6.7 mg/dL
AST, 30 units/L
ALT, 16 units/L
Total bilirubin, 1 mg/dL
Platelets, 95,000/μL
Hematocrit, 38%
Hemoglobin, 13 g/dL
Random urine protein, 4+

Estimated fetal weight by ultrasound is 1,700 g, which is between the 10th and 25th percentile for a gestational age of 34 weeks. What signs, symptoms, and laboratory evidence of severe preeclampsia support this diagnosis in T.D., and what complications may occur?

T.D. has developed severe preeclampsia.[84] Her systolic and diastolic BP are greater than 160 and 112 mm Hg, respectively. She has greater than 3+ protein in a random urine sample, and her SCr is elevated. She complains of headaches and visual disturbances. T.D. is also thrombocytopenic as her platelet count is 95,000/μL. Although her liver transaminases are currently normal, she may be developing HELLP syndrome, a variant of severe preeclampsia associated with a high incidence of maternal and perinatal morbidity and mortality. Therefore, her laboratory values should continue to be monitored even as delivery is being planned.

COMPLICATIONS

T.D. is at risk for cerebral hemorrhage, cerebral edema, encephalopathy, coagulopathies, pulmonary edema, liver failure, renal failure, and eclamptic seizures.[85,86] Severe preeclampsia is dangerous not only to T.D. but also to her fetus because uteroplacental perfusion is compromised. T.D. requires drug treatments to both lower her BP and prevent eclampsia, as well as delivery.

ACUTE TREATMENT OF SEVERE HYPERTENSION

CASE 49-5, QUESTION 9: How should T.D.'s severe hypertension be treated?

The goal of antihypertensive therapy in T.D. is to prevent cerebral complications (e.g., encephalopathy, hemorrhage).[85] Although it is important to reduce the maternal BP, it must be accomplished gradually while the fetus is in utero because a sudden large drop in maternal BP could result in the reduction of uteroplacental perfusion.[86] Because of the potential for fetal bradycardia during or after acute treatment of maternal hypertension, continuous fetal heart rate monitoring should be considered.

Hydralazine

Hydralazine, a direct arterial smooth muscle dilator, has in the past been the drug of choice for the acute treatment of severe hypertension in pregnancy.[85,91] This drug induces a baroreceptor-mediated tachycardia and increases cardiac output, which increases uterine blood flow because the BP is lowered.[86]

The onset of antihypertensive effect for hydralazine ranges from 10 to 20 minutes, and duration of action ranges from 3 to 6 hours after an IV dose.[86,100] Therefore, doses of hydralazine should not be repeated more frequently than every 20 to 30 minutes to prevent drug accumulation.[91] Nausea, vomiting, tachycardia, flushing, headache, and tremors could occur. Some of these hydralazine-induced adverse effects mimic symptoms associated with severe preeclampsia and imminent eclampsia, making it difficult for a clinician to differentiate between drug-associated and disease-related problems.[91] Fetal hydralazine serum concentrations are reportedly the same as or higher than maternal serum concentrations, but drug-associated fetal abnormalities have not been reported.[38]

Labetalol

Labetalol is also a commonly used drug to treat severe hypertension during pregnancy. It should be administered IV in increasing doses of 20, 40, and 80 mg every 10 minutes to a cumulative dose of 300 mg or until the diastolic pressure is less than 100 mm Hg.[101] The onset of action is within 5 minutes, and its effect peaks in 10 to 20 minutes with a duration of action ranging from 45 minutes to 6 hours.

IV labetalol is as effective as IV hydralazine in lowering BP in patients with hypertension during pregnancy, but has fewer reported adverse effects.[91–102] In a meta-analysis of β-blocker trials for the treatment of hypertension in pregnancy, labetalol was associated with less maternal hypotension, fewer cesarean deliveries, and no increase in perinatal mortality.[102] Labetalol also does not appear to decrease uteroplacental blood flow even with a decrease in maternal BP.[91] Labetalol reduces cerebral perfusion pressure, which occurs in up to 43% of women with severe preeclampsia, without negatively affecting cerebral blood flow.[103] Decreased cerebral perfusion pressure may prevent progression to eclampsia. However, it should be avoided in women with asthma and decompensated heart failure.[104,105] Labetalol has also been associated with higher rates of neonatal bradycardia and hypotension than hydralazine, but not higher rates of neonatal intensive care admission.[106,107]

Nifedipine

Nifedipine has been used in doses of 10 mg for acute treatment of severe hypertension during pregnancy because it can be given orally.[91] Nifedipine is effective in decreasing BP without reducing uteroplacental blood flow or decreasing fetal heart rate. Short-acting nifedipine capsules are no longer recommended for the treatment of acute hypertensive urgency, however, because of the risk of stroke or myocardial infarction, and it was never FDA-approved for this indication. Immediate-release nifedipine continues to be used to treat hypertension in pregnancy, however, because this unique patient population may not be at high risk for ischemic events secondary to atherosclerotic disease.[88] Calcium gluconate or calcium chloride should be available for IV administration in the event of sudden hypotension. Caution should be used when giving nifedipine to women concomitantly treated with magnesium sulfate because these drugs have synergistic effects, causing hypotension and neuromuscular blockade.[106]

Several studies comparing immediate-release oral nifedipine with IV labetalol in hypertensive emergencies of pregnancy have found them to be equally effective in lowering BP.[107,108] Nifedipine lowers BP to less than 160 mm Hg systolic and less than 100 mm Hg diastolic earlier than labetalol,[107] but it increases cardiac index[108] (see Chapter 21, Hypertensive Crises). The use of sustained-release nifedipine capsules as an alternative is associated with a delay in BP control to 45 to 90 minutes, which is probably not acceptable.[100]

Hydralazine 5 mg IV for 1 to 2 minutes should be administered to T.D. and repeated in doses of 5 to 10 mg every 20 to 30 minutes to a cumulative dose of 20 mg.[85] T.D. should have repeated measurements of her BP at 15-minute intervals. Because intervillous blood flow depends on maternal perfusion pressure, the goal is to decrease the diastolic pressure to not less than 90 mm Hg.[85,100] Lowering the maternal BP excessively may decrease uteroplacental perfusion and compromise the fetus. A hypotensive overshoot can be observed with hydralazine, particularly in the setting of volume depletion, which is typical of preeclampsia.[100] If one or two doses of hydralazine are not effective in lowering T.D.'s diastolic to less than 100 mm Hg, labetalol 20 mg IV every 10 to 15 minutes can be given.

Eclampsia

MAGNESIUM SULFATE PROPHYLAXIS

CASE 49-5, QUESTION 10: T.D. will undergo an induction of labor for her severe preeclampsia. Which medication should be given to T.D. to prevent seizures?

The precise mechanism of anticonvulsant action of magnesium for the prevention and treatment of eclamptic seizures is unknown. The anticonvulsant activity may be partly mediated through blockade of an excitatory amino acid receptor, N-methyl-D-aspartate.[106] Seizures are thought to be caused by decreased cerebral blood flow because of vasospasm. Magnesium sulfate is a potent cerebral vasodilator and increases the synthesis of prostacyclin, an endothelial vasodilator. It also causes a dose-dependent decrease in systemic vascular resistance, which may explain its transient hypotensive effect. Magnesium may also protect against oxidative injury to endothelial cells.[106]

Although termination of the pregnancy is the definitive treatment for severe preeclampsia, the intrapartum and immediate postpartum periods are also the periods of greatest risk for eclampsia.[84] Although the incidence of eclampsia is extremely low, maternal morbidity and mortality are high.[109] In the United States, it has been usual practice to treat all preeclamptic women with magnesium sulfate during labor and for 12 to 24 hours postpartum.[80,85] In the United Kingdom, however, it is common to reserve magnesium sulfate therapy for severe preeclampsia.[110] The evidence for magnesium sulfate prevention of the progression of disease in mildly preeclamptic women had been largely anecdotal in the past. In a large international study of more than 10,000 women, published in 2002, magnesium sulfate clearly decreased the risk of eclampsia in preeclamptic women by 58% compared with placebo.[110] An observational study of nearly 2,500 women with mild preeclampsia (BP of 140/90 mm Hg and 1+ protein) found an incidence of eclampsia of about 1% without the use of seizure prophylaxis.[111]

In a prospective, randomized study, magnesium sulfate was superior to phenytoin for the prevention of eclampsia in hypertensive pregnant women.[109] In addition, magnesium sulfate was more effective than nimodipine for seizure prophylaxis in severely preeclamptic women.[112,113]

A regimen of magnesium sulfate 4 to 6 g IV as a loading dose followed by a continuous infusion of 2 g/hour is the most commonly used regimen in the United States.[115] Lower dosages (e.g., 1 g/hour) have been associated with treatment failures.[116] IV loading doses of 6 g followed by continuous infusions of 2 g/hour maintain therapeutically effective magnesium serum concentrations between 4 and 8 mg/dL.[115] Because magnesium is excreted by the kidneys and will accumulate in cases of renal dysfunction, the continuous infusion rate must be lowered with oliguria or an elevated SCr.

Because of the potential for infusion errors and significant patient morbidity and even mortality with accidental overdoses of magnesium sulfate, the Institute of Medicine has identified magnesium sulfate as a high-risk medication.[116] All infusions of magnesium sulfate must be given through a controlled pump designed to protect against free flow. If such an infusion pump is not available, the intramuscular (IM) route of administration should be used. Dispensing premixed IV bags from the central pharmacy with a standardized concentration of magnesium sulfate and limiting the total grams of magnesium sulfate in each dispensed IV bag also can help guard against inadvertent overdose. Dispensing the loading dose in a separate small bag (e.g., 4 g in 100 mL) from the maintenance bag (e.g., 20 g in 200 mL) also may be helpful.[117]

Magnesium sulfate should be given to T.D. to prevent eclamptic seizures during labor.[80] T.D. should be loaded with magnesium sulfate 4 g IV given for 30 minutes and then started on a continuous infusion of 2 g/hour.

MONITORING MAGNESIUM SULFATE THERAPY

CASE 49-5, QUESTION 11: T.D. has been given magnesium sulfate 4 g IV for 30 minutes and was then started on a continuous infusion of 2 g/hour. What subjective and objective data should be monitored during treatment of T.D. with magnesium?

Deep tendon reflexes (patellar reflex), respiratory rate, and urine output should be monitored periodically during treatment with magnesium sulfate.[109] The loss of patellar reflexes, the first sign of magnesium toxicity, generally occurs at serum concentrations of

---

8 to 12 mg/dL. The respiratory rate should be monitored hourly and should be greater than 12 breaths/minute. Respiratory arrest can occur with serum concentrations of greater than 13 mg/dL. Urine output should be carefully monitored and should be at least 100 mL every 4 hours (or 25 mL/hour).[109] Magnesium serum concentrations are not routinely measured unless renal dysfunction is evident with

oliguria or elevated SCr because magnesium is almost entirely excreted by the kidney.[106,109] Hypocalcemia and hypocalcemic tetany also can occur secondary to elevated magnesium and can be reversed by calcium gluconate 1 g (10 mL of a 10% solution) slow IV push for 3 minutes. Neuromuscular depression can occur in infants whose mothers received magnesium sulfate.[38] Parenteral magnesium sulfate is safe and rarely causes maternal or neonatal toxicity when administered properly but requires stringent, built-in system safeguards to avoid unintended dosing errors.[117]

CASE 49-5, QUESTION 12: How long should magnesium sulfate be continued in T.D.?

Depending on the severity of preeclampsia, magnesium sulfate therapy usually is continued for 24 hours after delivery, which should be the same for T.D.[118] Women with severe preeclampsia or preeclampsia superimposed on chronic hypertension are at greater risk for disease exacerbation when magnesium sulfate is discontinued too soon.

TREATMENT OF ECLAMPSIA

CASE 49-5, QUESTION 13: T.D. delivers vaginally and her magnesium infusion was discontinued by mistake 3 hours postpartum. T.D. experiences an eclamptic seizure 4 hours later when her nurses discover that the magnesium is disconnected. What is appropriate drug therapy for eclampsia?

Lorazepam, diazepam, phenytoin, and magnesium sulfate have all been used to treat eclampsia. The use of magnesium sulfate to treat these seizures results in less maternal morbidity and mortality and less neonatal morbidity.[109,119] Generally, higher serum concentrations of magnesium sulfate are needed to treat than to prevent eclamptic seizures. The same therapeutic range guides both prophylaxis and treatment, however.[114] Seizures unresponsive to magnesium sulfate treatment should prompt an evaluation for other cerebrovascular events (e.g., cerebral hemorrhage or infarction).[115] Lorazepam 2 to 4 mg slow IV push stat should be given for seizure cessation. T.D. should be reloaded with magnesium sulfate and continued on a magnesium infusion for 24 to 48 hours.

DRUG THERAPY MANAGEMENT IN LABOR AND DELIVERY

Induction of Labor

MECHANISMS OF TERM LABOR

In pregnancy, many hormones and peptides, including progesterone, prostacyclin, relaxin, nitric oxide, and parathyroid hormone-related peptide, inhibit uterine smooth muscle contractility. Labor at term occurs because the myometrium is released from its quiescent state.[120] For example, as progesterone concentrations decrease near term gestation, estrogen may stimulate uterine contractility.

Uterine activity is divided into four phases: quiescence (phase 0), activation (phase 1), stimulation (phase 2), and involution (phase 3). Each of these phases is stimulated or inhibited by several factors.[120] During activation, uterotropins such as estrogen, and possibly others, stimulate a complex series of uterine changes (e.g., increased myometrial prostaglandin and oxytocin receptors and myometrial gap junctions), which are important for the coordination of contractions. These changes help prime the myometrium and cervix for stimulation by the uterotonins oxytocin and prostaglandins E_2 and $F_2\alpha$. The cervix softens, shortens, and dilates, a process referred to as cervical ripening. Uterine stimulation is responsible for the change in myometrial activity from irregular to regular contractions. During phase 3, involution of the uterus occurs after delivery and is mediated mostly by oxytocin.[120]

The exact stimulus of the biochemical scheme leading to labor in humans is unknown. The fetus may help facilitate this process by affecting placental steroid production through mechanical distension of the uterus and by activating the fetal hypothalamic–pituitary–adrenal axis. Ultimately, these lead to increased production of oxytocin and prostaglandins by the fetoplacental unit.

Labor is divided into three stages. Weak, irregular, rhythmic contractions (Braxton-Hicks contractions or "false labor") may happen for weeks before the onset of true labor. The first stage begins with the start of regular uterine contractions and ends with complete cervical dilation. Stage 1 is divided further into the latent phase, active phase, and deceleration phase. During the latent phase, the cervix effaces (thins) but dilates minimally. The contractions become progressively stronger and longer, better coordinated, and more frequent. The duration of the latent phase is the most varied and unpredictable of all aspects of labor, and can continue intermittently for days. During the active phase, contractions are strong and regular, occurring every 2 to 3 minutes. The cervix dilates from 3 to 4 cm to full dilation, usually 10 cm. The second stage starts with complete cervical dilation and ends with the delivery of the fetus. The third stage of labor is the time between the delivery of the fetus and the delivery of the placenta.

INDICATIONS, CONTRAINDICATIONS, AND REQUIREMENTS

CASE 49-6

QUESTION 1: J.T., a 28-year-old primigravida, is admitted to the labor and delivery suite for labor induction. She is at 42 weeks' gestation by dates and ultrasound and has a normal obstetric examination. Cervical examination reveals an unfavorable cervix for labor induction; Bishop score is 4. What are the indications and contraindications for labor induction in J.T.?

The induction of labor involves the artificial stimulation of uterine contractions that lead to labor and delivery. Induction of labor is indicated when the benefits to either the mother or fetus outweigh those of continuing the pregnancy. Examples may include preeclampsia, chorioamnionitis (infection of the fetal membranes, see Case 49-7, Question 11), fetal demise, significant fetal growth restriction, maternal medical problems, and post-term pregnancy.[121] Post-term pregnancy (≥42 weeks' gestation), as in J.T.'s case, is one of the most common indications for induction of labor.[121] Contraindications to labor induction are similar to those for spontaneous labor and vaginal delivery and include, but are not limited to, active genital herpes infection, placenta previa (placenta implanted over the internal cervical opening), prior classic uterine incision, transverse fetal lie (laying longitudinally across the uterus), and prolapsed umbilical cord. Maternal complications that are associated with induction include increased rates of chorioamnionitis and uterine atony (loss of tone in uterine musculature) (see Case 49-8, Question 4) resulting in hemorrhage, as well as a twofold to threefold increased risk of cesarean delivery, particularly in primigravida women.[122]

A complete assessment of both mother and fetus should be performed before inducing labor.[121,123] Gestational age must be assessed accurately before the induction of labor to avoid the inadvertent delivery of a preterm fetus.[121,122] When delivery is necessary before 34 weeks' gestation with intact membranes or before 32 weeks' gestation with ruptured membranes, antenatal corticosteroids should be administered (see Case 49-7, Question 7).[123,124]

The degree of cervical ripeness and readiness for induction of labor should be assessed.[121,125] Success of labor induction is directly related to the favorability of the cervix.[126,127] The Bishop method of evaluating cervical ripeness assigns a score based on the station of the fetal head relative to the maternal ischial spines and the extent of cervical dilation, effacement (thinning of the cervix), consistency, and position.[122,125] Bishop scores of greater than 8 are associated with rates of vaginal delivery similar to those after spontaneous labor.[121] Conversely, Bishop scores of 4 or less, as documented in J.T., are associated with a high likelihood of failed induction and cesarean delivery. As a result, significant research has been directed toward methods of improving the Bishop score and cervix ripeness before stimulation of uterine contractions. However, women with low Bishop scores who undergo cervical ripening before induction of labor still have higher rates of cesarean delivery compared with spontaneous labor.[126] Nevertheless, cervical ripening appears to have some benefit in decreasing time to delivery, shortening labor, and successfully improving Bishop score.[121]

Cervical ripening can be accomplished pharmacologically or mechanically. Pharmacologic methods include the administration of prostaglandins (E_2 and E_1) or low-dose oxytocin. Mechanical methods include membrane sweeping (or membrane stripping), and intracervical balloons.[121,123,125] Osmotic or hygroscopic dilators (e.g., Dilapan, Lamicel) work by absorbing cervical mucus and gradually swelling, thereby dilating the cervical canal.[122,125] In the setting of a favorable Bishop score, labor induction is accomplished most commonly by amniotomy (artificial rupture of the fetal membranes) and oxytocin administration.[121,122]

Although labor induction is medically indicated in J.T. to decrease the risk of an adverse fetal outcome with continuing a post-term pregnancy, such as macrosomia, asphyxia, meconium aspiration, and intrauterine infection, her cervix is unfavorable for induction and she is a candidate for cervix ripening.

CERVICAL RIPENING

CASE 49-6, QUESTION 2: What pharmacologic agents can be used for cervical ripening in J.T.?

Misoprostol (Cytotec)

Prostaglandins induce cervical ripening and enhance myometrial sensitivity to oxytocin by promoting the breakdown of collagen and increasing the submucosal hyaluronic acid and water content.[121,122,125] Misoprostol is a prostaglandin E_1 analog approved for use in the prevention of nonsteroidal anti-inflammatory drug-induced peptic ulcer disease. It also has been used for cervical ripening and the induction of labor in women despite the lack of approval by the FDA for these latter indications.[128,129] In two large meta-analyses, misoprostol was more effective for cervical ripening and labor induction than either placebo or treatment with dinoprostone (prostaglandin E_2).[128,129] In comparisons, intravaginal misoprostol produced labor more often during cervical ripening and resulted in reduced rate of cesarean deliveries, shorter delivery times, and a greater incidence of vaginal delivery within 24 hours but had a higher incidence of uterine contraction abnormalities than either dinoprostone vaginal insert or dinoprostone endocervical gel.[128–132] Uterine tachysystole, excessively frequent uterine contractions, without fetal heart rate abnormalities was more common with misoprostol use. Maternal and neonatal outcomes were similar in both groups. The need for oxytocin is decreased significantly in women treated with misoprostol compared with women treated with dinoprostone.[131]

Oral misoprostol has also been studied for cervical ripening, but comparisons of vaginal and oral misoprostol are complicated by wide variations in dose and dose interval.[132] A meta-analysis of available studies concluded that the only consistent finding was a reduction in low 5-minute Apgar scores with oral misoprostol but no difference in neonatal intensive care unit admissions. When comparing all studies with a wide range of doses, oral misoprostol resulted in similar rates of vaginal delivery not achieved in 24 hours, uterine tachysystole with fetal heart rate changes, and cesarean delivery compared with vaginal misoprostol.[122]

Misoprostol 25 mcg (one-fourth of an unscored 100-mcg tablet) is inserted into the posterior vaginal fornix and repeated as needed every 3 to 6 hours.[130,131] Higher doses of 50 mcg are associated with increased uterine contractile abnormalities.[128,132] Continuous fetal heart rate and uterine monitoring is recommended throughout the administration of misoprostol.[133] If oxytocin is indicated after cervical ripening, administration should be delayed at least 4 hours from the last dose of misoprostol.[121]

Misoprostol should not be used in women with previous uterine scars because of the risk for uterine rupture.[121,130,132] Although misoprostol is a known teratogen in the first trimester of pregnancy, particularly if used in an unsuccessful attempt at medical abortion, there are no such reports with exposure beyond the first trimester.[38,130] Misoprostol's low cost and ease of administration are advantages compared with dinoprostone, and there is extensive clinical experience with this agent; however, its lack of FDA approval for cervical ripening and induction of labor is a disadvantage. Clinical trials of a controlled-release misoprostol vaginal insert are currently ongoing.[133]

Prostaglandin E^2 (Dinoprostone)

There are two FDA-approved forms of dinoprostone available for cervical ripening. Up to half of the women treated with dinoprostone experience labor and deliver within 24 hours, some without oxytocin.[134,136] Dinoprostone cervical gel (Prepidil Gel) contains dinoprostone contains 0.5 mg per 3-g syringe (2.5 mL gel) and is administered endocervically. The dinoprostone cervical gel must be refrigerated, and dinoprostone vaginal inserts must remain frozen until administration. Dinoprostone slow-release insert (Cervidil) contains dinoprostone 10 mg and is inserted vaginally.[137] Post-term women with unfavorable cervices who receive dinoprostone have shorter durations of labor, and require lower doses of oxytocin, compared with placebo or no therapy.[125,134–136] A large meta-analysis that included more than 10,000 women found that the use of vaginal prostaglandin E_2 compared with no treatment or placebo was associated with increased rates of vaginal delivery within 24 hours, increased rates of cervix ripening, reduced need for oxytocin augmentation, and no difference in cesarean section. The risk of uterine tachysystole with fetal heart rate changes was increased, however.[138]

Both dinoprostone products are effective for cervical ripening, leading to successful induction of labor.[125,134–136] The two dinoprostone formulations differ in dosing and application.[139,141] The dinoprostone 10-mg vaginal insert slowly releases dinoprostone 0.3 mg/hour for a 12-hour period.[137] The insert is contained within a knitted pouch attached to a long tape. Advantages of the vaginal insert include that it is easier for the clinician to place and less uncomfortable for the patient. In addition, the insert can be removed with the onset of active labor or the development of uterine tachysystole with concurrent fetal heart rate tracing abnormalities. It should be removed within 12 hours of placement or after active labor develops, the membranes rupture, or there is evidence of tachysystole with fetal heart rate changes.[141] If dinoprostone cervical gel is used, the dose can be repeated in 6 to 12 hours if there is inadequate change in the cervix and only minimal uterine activity, but no more than three total doses are recommended.[141] The manufacturer of Prepidil recommends a delay in initiation of oxytocin of 6 to 12 hours once the gel has been placed compared with a shorter delay of only 30 to 60 minutes after the vaginal insert has been removed. An initial period of uterine and fetal monitoring of up to 2 hours should occur after placement of the intracervical gel, with continued monitoring thereafter if regular uterine contractions develop and persist.[121]

The most serious side effect associated with dinoprostone administration is uterine hyperstimulation with or without an abnormal fetal heart rate tracing. The incidence of uterine hyperstimulation associated with the use of dinoprostone intravaginal insert is about 5%; the rate of occurrence for dinoprostone endocervical gel is about 1%.[121] Uterine hyperstimulation occurs more frequently if the Bishop score is greater than 4 before administration of dinoprostone and can occur up to 9.5 hours after placement of the intravaginal insert.[121,141] Use of the vaginal insert requires continuous monitoring of fetal heart rate and uterine activity for as long as the insert is in place and for at least 15 minutes after its removal because of possible uterine hyperstimulation anytime during its administration.[135] Most episodes of uterine hyperstimulation with the use of the vaginal insert occur during active labor and resolve within a few minutes after removal of the insert.[136] Uterine contraction abnormalities may be avoided if the insert is promptly removed at the onset of labor.[128] Both dinoprostone formulations are associated with fever, nausea, vomiting, and diarrhea, and neither are associated with adverse neonatal outcomes.[121,137,139]

For J.T., misoprostol 25 mcg should be administered intravaginally every 3 to 6 hours for cervical ripening. Misoprostol is the most cost-effective option for cervical ripening.

OXYTOCIN

Mechanism of Action

CASE 49-6, QUESTION 3: Twelve hours after administration of two 25-mcg doses of misoprostol, J.T.'s cervix has responded and her Bishop score is now 9, but she has not developed a consistent pattern of uterine contractions. What drug therapy should be initiated at this point?

Synthetic oxytocin should be administered to J.T. to stimulate uterine contractions for accomplishing delivery. Oxytocin increases the frequency, force, and duration of uterine contractions.[142] The uterine response to oxytocin increases throughout pregnancy beginning at approximately 20 weeks' gestation and increases considerably at 30 weeks' gestation.[140] Oxytocin is indicated for both the induction and augmentation of labor. A prolonged latent phase or dystocia (difficult labor) caused by uterine hypocontractility in the active phase of labor is the indication for augmentation with oxytocin.[140]

Dosing and Administration

CASE 49-6, QUESTION 4: How should oxytocin be administered to J.T.?

Oxytocin should be administered by continuous IV infusion using a controlled infusion device. The goal of oxytocin administration is to induce uterine contractions that dilate the cervix and aid in the descent of the fetus while avoiding uterine hyperstimulation and fetal distress.[142] There are two opposing views about oxytocin administration for the induction or augmentation of labor. One view is that oxytocin infusions should mimic physiologic doses in the range of 2 to 6 milliunits/minute with the goal being vaginal delivery with as little uterine hyperstimulation and fetal distress as possible.[121] The other view is that oxytocin should be used in pharmacologic doses to cause strong uterine contractions with the goals being shortened labor, timely correction of dysfunctional labor, decreased cesarean deliveries, and reduced maternal morbidity.[121]

Oxytocin plasma concentrations increase linearly with increasing doses, and steady state is reached within 20 to 40 minutes. Oxytocin serum concentrations correlate poorly with uterine activity, however.[143] Factors that may affect response to oxytocin include parity, gestational age, and cervical dilation.[143]

Despite many randomized, controlled trials and much experience with oxytocin, the optimal starting doses, dosage increments, dosing intervals, and maximal doses are different in the various protocols.[140,142,144] Starting doses range from 0.5 to 6 milliunits/minute, and dose increment intervals range from 15 to 60 minutes.[121] Waiting for 30 to 40 minutes between each dosage rate increase allows time to assess the response at steady state. Most low-dose protocols usually start oxytocin 1 to 2 milliunits/minute and increase the rate of infusion by 1 to 2 milliunits/minute every 30 to 40 minutes.[142,145] High-dose protocols start oxytocin at 3 to 6 milliunits/minute with incremental increases of 3 to 6 milliunits/minute every 20 to 40 minutes. The maximal dose of oxytocin has not been established.[121] The ACOG recommends that each hospital's obstetrics departments develop guidelines for the consistent preparation and administration of oxytocin.[121]

Oxytocin protocols using higher doses or shorter dose adjustment intervals (15–20 minutes) for augmentation of labor generally result in fewer cesarean deliveries for labor dystocia, which is an abnormally slow progress of labor.[145–147] The incidence of uterine hyperstimulation during labor induction is higher with high-dose protocols (initial dose of 6 milliunits/minute with incremental increases of 6 milliunits/minute), however, when compared with shorter dosing adjustment intervals of 20 minutes or with longer dose adjustment intervals of 40 minutes.[147] Women undergoing labor induction with high-dose oxytocin have a higher incidence of uterine stimulation and cesarean deliveries for fetal distress, but a reduced incidence of failed inductions and neonatal sepsis compared with women treated with low-dose oxytocin.[147] In general, lower maximal doses are needed for augmentation of labor than for induction of labor.[144,148]

J.T. should be started on an infusion of oxytocin 10 units diluted in 1,000 mL of an isotonic solution (concentration 10 milliunits/mL) at 1 milliunits/minute. She should have continuous uterine and fetal heart rate monitoring throughout the infusion to detect abnormal uterine contraction patterns or fetal heart rate patterns. The goal is to establish a pattern of three to five uterine contractions of 60 to 90 seconds' duration per 10-minute period.[146] The oxytocin infusion should be increased by 1 to 2 milliunits/minute every 30 to 40 minutes as needed for inadequate progression of labor (cervical dilation rate of <1 cm/hour).[121,149] Fluid intake and urine output should be assessed hourly.

Adverse Effects

CASE 49-6, QUESTION 5: What are the adverse effects and complications of oxytocin for which J.T. should be monitored?

Uterine hyperstimulation, usually associated with excessive maternal dosing or increased myometrial sensitivity to oxytocin, may result in uterine rupture, vaginal and cervical lacerations, precipitous delivery, abruptio placentae, emergency cesarean delivery for fetal distress, and postpartum hemorrhage secondary to uterine atony. In general, neonatal outcomes associated with oxytocin use do not differ from those achieved by spontaneous

---

labor.[146] Although oxytocin has only weak antidiuretic properties, water intoxication resulting in seizures, coma, and death has been reported.[121] Oxytocin is structurally and functionally related to vasopressin, also known as antidiuretic hormone. Administration of high concentrations of greater than 40 milliunits/minute and for long periods is associated with hyponatremia, which can lead to lethargy, drowsiness, generalized seizures, and potentially irreversible neurologic injury. IV bolus administration may cause paradoxical relaxation of vascular smooth muscle leading to hypotension and tachycardia. J.T. should be monitored for uterine hyperstimulation with fetal heart rate deceleration because it is the most common adverse effect of oxytocin.[121,142]

Preterm Labor

Preterm delivery occurred in 12.8% of births in the United States in 2006, representing a 20% increase since 1990.[3] Approximately 55% of singleton preterm births follow spontaneous preterm labor, and approximately 8% follow preterm premature rupture of the chorioamniotic membranes.[150] Premature birth is the leading cause of neonatal mortality (infant death <1 month of age), resulting in approximately 70% of deaths.[150] Prematurity is the second leading cause of infant mortality at younger than 1 year of age, and resulted in 17% of such deaths in 2006.[8] However, the more inclusive classification of mortality as being "preterm related" was linked to 36.1% of all infant deaths in 2006.[8]

ETIOLOGY

Spontaneous preterm labor is a heterogeneous syndrome, and several known pathways can lead to preterm birth. These pathways include excessive uterine distension, decidual hemorrhage, activation of the maternal and fetal hypothalamic–pituitary system, and intrauterine infection leading to inflammation. These pathways ultimately lead to a final common response with production of uterine and cervical proteases and uterotonins, which result in progressive cervical ripening and dilation; weakening of the chorioamniotic membranes, which leads to rupture; and uterine contractions. Ultimately, delivery of the infant occurs. Infection, if present, triggers an inflammatory response that results in the release of cytokines, prostaglandins, and proteases, which stimulate uterine activity, induce cervix softening and dilation, and weaken the chorioamniotic membranes.[152] Variations in maternal and fetal genes coding for cytokines have been implicated in the apparent genetic predisposition to preterm birth found in some families and racial groups.[153] Thrombin is another uterotonic agent, which can cause uterine contractions, and has been implicated in causing preterm labor associated with vaginal bleeding caused by placental abruption.[154] Studies have shown a relationship between increasing maternal corticotropin-releasing hormone (CRH) and delivery timing.[155] Maternal and fetal stress can activate the hypothalamic–pituitary system and result in the rapid increase of maternal CRH before premature birth. Infection can also activate the fetal hypothalamic–pituitary system, increasing CRH, cortisol, and, ultimately, prostaglandins.[152,154] Despite some progress in recent years, much remains unknown about the etiology of preterm birth, and little is known about how preterm birth can be prevented.

CLINICAL PRESENTATION AND EVALUATION

CASE 49-7

QUESTION 1: B.B., a 17-year-old white woman, G2, P1, and 29 weeks' gestation, is admitted to the obstetric unit with complaints of backache, cramps, and uterine contractions. She has no symptoms of preterm premature rupture of the membranes (PPROM). She had a previous preterm birth at 32 weeks' gestation. Cervicovaginal secretions are positive for fetal fibronectin. A pelvic examination reveals that her cervix is 2 cm dilated and 80% effaced, which is increased from 1 cm at her prenatal visit last week. Cervical cultures for Chlamydia trachomatis and Neisseria gonorrhoeae from her previous visit are negative. Vaginal wet-mount preparations are also negative for bacterial vaginosis and Trichomonas vaginalis. Vital signs, urinalysis, and complete blood count with differential are normal. Uterine contractions and fetal heart rate are being monitored. Ultrasound reveals a fetus of 30 weeks' gestation size with an estimated weight of 1,200 g. What signs, symptoms, and laboratory evidence support a diagnosis of preterm labor?

B.B. has backache and uterine contractions, which are symptoms of preterm labor. Most women with preterm contractions are not in labor, however, which results in frequent overdiagnosis. In addition, contractions during preterm labor are frequently not painful, are not detected by the woman, and thus are not a sensitive marker for preterm labor. Fibronectin, a protein that serves as an adhesive between the fetal membranes and decidua, normally disappears from the cervical secretions after the first half of pregnancy, reappearing only at term as labor approaches.[156] A negative fibronectin test can exclude imminent preterm delivery in a woman at risk for preterm delivery, between 24 and 34 weeks' gestation with intact amniotic membranes, and with cervical dilatation of less than 3 cm.[157] Because of fibronectin's high negative predictive value of greater than 95% for delivery in the next 1 to 2 weeks, it can be used to avoid overdiagnosis of preterm labor. Although fibronectin testing will yield false-positive results in the presence of blood, vaginal bleeding itself is independently associated with preterm birth. B.B. has the criteria necessary to establish a firm diagnosis of preterm labor. Not only is her fibronectin test positive, but she has persistent contractions with a documented change in cervix dilatation.

RISK FACTORS

CASE 49-7, QUESTION 2: What risk factors does B.B. have for spontaneous preterm labor?

B.B. has several risk factors for preterm delivery. The strongest predictor of preterm birth is prior preterm birth. She has a twofold or higher increased risk of preterm delivery because of one previous preterm delivery.[156] If this pregnancy also ends prematurely, her risk for a third preterm birth in her next pregnancy will be sixfold higher than that in the normal population.[156] Recurrence risk rises as the gestational age of the prior preterm birth decreases, especially for deliveries at less than 32 weeks. Her young age may also be a risk factor. A maternal age younger than 18 or older than 35 years is associated with spontaneous preterm birth, although it is difficult to separate age from the confounding factors associated with age.[156] Her race likely does not contribute to her risk. Black race is an independent risk factor for both preterm labor and lower neonatal birth weight. Other risk factors include low maternal weight before pregnancy, smoking, second- or third-trimester bleeding, multiple gestation, and uterine anomalies, which B.B. does not have.[120,156] Studies of cervix length by transvaginal ultrasound imaging have demonstrated that shorter lengths are associated with greater risk for preterm delivery; however, the positive predictive value varies widely.[156,157] Maternal infections, such as untreated urinary tract infections and pneumonia, are associated with preterm delivery. In addition, genital organisms such as Gardnerella vaginalis, C. trachomatis, N. gonorrhoeae, Ureaplasma urealyticum, and T. vaginalis, are also associated with preterm births.[142] Although it is important to identify women at risk for spontaneous preterm delivery, only half of all preterm deliveries occur in women with known risk factors.[156]

TOCOLYSIS

Goals of Therapy

CASE 49-7, QUESTION 3: What are the goals of tocolysis for B.B.?

Treatment of spontaneous preterm labor primarily has been directed at slowing or stopping contractions (tocolysis), which are the obvious, although likely late, sign of impending preterm birth. It has been presumed that if successful, this should prevent or delay preterm birth. Few placebo-controlled trials have been conducted of agents used to diminish contractions (tocolytics), and most data suggest delay of delivery by at most 1 to 2 days.[158] This might be because of the heterogeneous causes of spontaneous preterm birth and because tocolytic agents may not arrest the underlying process that led to contractions. Most studies have been unable to demonstrate a clear benefit of tocolysis on neonatal morbidity and mortality. Instead, they have evaluated surrogate end points, such as pregnancy prolongation or number of preterm births before various cut-off points.[159] The value of prolonging pregnancy will vary by gestational age, and might be substantial if time is gained to administer glucocorticoids to improve fetal lung maturation and decrease the risk of intraventricular hemorrhage (see Case 49-7, Question 7). All women at risk for preterm birth within 7 days and between 24 and 34 weeks' gestation should be considered for glucocorticoid therapy.[124,159,160] Delay of delivery can also allow transport to a facility best equipped to care for both mother and premature newborn.

Numerous factors affect the decision to treat preterm labor with a tocolytic agent. Fetal factors precluding tocolysis include nonreassuring fetal monitoring, significant IUGR, and lethal congenital anomalies. Maternal factors include evidence of chorioamnionitis, other significant maternal infections or illness, preeclampsia, and advanced labor.[156] Tocolysis is less likely to be effective in women with cervical dilation of greater than 3 cm and is usually unsuccessful if the patient is in advanced labor (cervical dilation >5 cm).[156] Because the etiology of preterm labor is multifactorial, B.B. should be evaluated thoroughly and periodically for potential causes of preterm labor and treated appropriately when diagnosed. For example, urinary tract infections are associated with preterm labor, and they should be diagnosed and treated if present.[156] Additionally, some would also perform amniocentesis to exclude subclinical chorioamnionitis as a cause of preterm labor before initiating or continuing tocolysis, and to evaluate lung maturity at later gestational ages.[160] B.B. has no evidence of overt infection or other complications, and has no contraindications to tocolysis. Prolonging gestation, even for a few days, would be beneficial because B.B. is only at 29 weeks' gestation.

TOCOLYTIC AGENTS

CASE 49-7, QUESTION 4: How should B.B.'s preterm labor be managed? Which tocolytic agent should be used?

Magnesium Sulfate

Magnesium sulfate is the most frequently used parenteral tocolytic agent in the United States and is also prescribed for the prevention and treatment of eclampsia. Magnesium sulfate relaxes uterine smooth muscle at maternal serum levels of 5 to 8 mg/dL.[156] The mechanism by which it exerts this effect is not understood completely, but involves inhibition of myosin light-chain kinase activity by competition with intracellular calcium, reducing myometrial contractility.[159]

Despite its widespread use, the evidence for magnesium's efficacy in prolonging gestation is inadequate. In two published, randomized, placebo-controlled trials, no benefit in mean prolongation of pregnancy or mean neonatal birth weight was demonstrated. In meta-analyses of both placebo-controlled trials of magnesium for tocolysis compared with other active drugs, no prolongation of pregnancy was seen with magnesium.[158,161] Several small randomized, controlled studies have directly compared magnesium with parenteral β-adrenergic agonists, mostly ritodrine.[158] Three of the four showed no differences in birth outcomes. One of the four suggested prolonged pregnancy with magnesium added to ritodrine compared with ritodrine alone. Studies on the efficacy of β-adrenergic agonists (mostly ritodrine) versus placebo have been mixed, but on balance suggest delay of delivery for 48 hours, but not for 7 days. Therefore, because most trials comparing magnesium with β-adrenergic agonists did not show differences, it has been presumed that magnesium is equally effective. Magnesium is better tolerated than the β-adrenergic agonists, with fewer maternal side effects.[158] Magnesium is contraindicated in patients with myasthenia gravis and must be used with caution in renal failure.

β-Adrenergic Agonists

β-Adrenergic agonists are not the first-line choice for preterm labor because of high costs and the significant potential for maternal adverse effects described subseequently.[156,158] Both ritodrine, the only medication approved by the FDA for the treatment of preterm labor, and terbutaline bind to β_2-adrenergic receptors in uterine smooth muscle and ultimately inhibit smooth muscle cell contractility. Results of randomized, controlled trials of ritodrine have been mixed; however, a meta-analysis that included 1,320 women treated with β-agonists demonstrated fewer births at 48 hours but no change in number of births at 7 days. No benefit on neonatal morbidity or mortality was seen; however, the studies are limited by sample size.[162,163] The continued use of β-agonists can result in the development of tachyphylaxis to its effects on the myometrium and may in part explain treatment failures with these drugs.[156,163]

Terbutaline is available for IV, SC, and oral administration. One dose of terbutaline 0.25 mg SC is often administered to women with mild contractions and cervical dilation less than 2 cm. IV β-sympathomimetics are used in cases with more severe and frequent contractions and cervical dilation greater than 2 cm. However, because of potential adverse maternal side effects such as increased heart rate, transient hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema, and myocardial ischemia, the FDA issued a black box warning in 2011 against the use of injectable terbutaline beyond 48 to 72 hours. The FDA also recommended against any use of oral terbutaline for preterm labor owing to both lack of efficacy and the potential for significant maternal side effects.

β-Adrenergic Adverse Effects

β-Adrenergic agonists are not selective for myometrial β_2-adrenergic receptors at pharmacologic doses, and this accounts for their high incidence of adverse effects.[164] Maternal adverse effects such as pulmonary edema, palpitations, tachycardia, myocardial ischemia, hyperglycemia, hypokalemia, and hepatotoxicity result in discontinuation of therapy in up to 10% of patients.[156] Pulmonary edema can occur and, if not recognized promptly, can lead to ARDS and death.[156] β-Sympathomimetics should not be used in women with underlying cardiac disease or arrhythmias, hypertension, diabetes mellitus, severe anemia, or thyrotoxicosis.[156] In addition, these drugs should be avoided if there are signs of chorioamnionitis such as maternal leukocytosis, fetal tachycardia, or maternal fever.[155]

The most commonly reported fetal or neonatal adverse effects associated with β-agonist therapy include tachycardia, hypotension, hypoglycemia, and hypocalcemia, especially if the drug is being administered within hours of delivery.[156,164] Maternal hyperglycemia causing fetal hyperglycemia and hyperinsulinemia can lead

---

to neonatal hypoglycemia if not properly monitored postnatally. Fetal tachycardia rarely leads to fetal myocardial ischemia or hypertrophy.[164] In summary, although β-sympathomimetic drugs have been used commonly in the past, they are now used much less frequently because of side effect profiles and safety concerns.[156]

Indomethacin

Prostaglandins F_{2a} and especially E_2 are important regulators of myometrial contractility and cervical ripening.[120] Prostaglandin synthesis requires cyclooxygenase (COX), also known as prostaglandin synthetase, to convert arachidonic acid to prostaglandin G_2. COX inhibitors such as indomethacin decrease prostaglandin production, which decreases contractions and inhibits cervical change. As with other tocolytics, these drugs have not been adequately studied in multiple randomized controlled trials. A review of available randomized trials of indomethacin compared with placebo found significant reductions in women delivering at less than 37 weeks' gestation, an increase in gestational age at delivery, and a trend toward fewer deliveries at 48 hours and 7 days.[165] In three of eight trials comparing COX inhibitors with other tocolytics, a reduction in both delivery before 37 weeks' gestation and maternal drug reactions was noted. Also, seen in these studies was a trend toward a reduction in delivery within 48 hours.[165] Indomethacin is well tolerated, and GI upset can be mitigated by antacids when it occurs. The available studies are inadequately powered to evaluate neonatal safety and outcomes, however.[165,166]

Although well tolerated by the mother, concerns exist about the fetal and neonatal effects of prostaglandin synthetase inhibition. Indomethacin crosses the placenta rapidly, and fetal levels rapidly approach maternal levels.[164,166] Because indomethacin can decrease fetal urine output leading to oligohydramnios, the amniotic fluid index should be followed and indomethacin discontinued if it falls below 5 cm (normal range, 5–25 cm). Oligohydramnios generally resolves within 48 to 72 hours of the discontinuation of indomethacin. The fetal ductus arteriosus, which is critical to allow blood from the right ventricle to bypass the fluid-filled lungs, constricts in 25% to 50% of fetuses exposed to indomethacin in utero, but generally is reversible.[156] Permanent closure of the ductus arteriosus, however, can lead to fetal right heart failure and even intrauterine demise. The risk for neonatal adverse effects is increased with drug exposure of longer than 48 hours, as well as use after 32 weeks' gestation when premature closure of the ductus occurs more frequently.[156] An increased risk for maternal postpartum hemorrhage has also been reported with indomethacin use but did not reach significance in a meta-analysis.[165] Indomethacin should not be used in the presence of oligohydramnios or suspected fetal renal or cardiac anomaly (see Chapter 105, Neonatal Therapy).

More serious fetal and neonatal effects have been reported in some retrospective and observational studies, including neonatal necrotizing enterocolitis, intraventricular hemorrhage, and renal failure.[166-168] It is difficult, however, to discern whether these complications are causally related to indomethacin or to the use of the drug in cases of refractory preterm labor caused by subclinical intra-amniotic infection.[166,169] An analysis of the risks and benefits of indomethacin suggested its continued use as second-line treatment for preterm labor between 24 and 32 weeks' gestation in women with contraindications to other tocolytics.[166] Typical dosing regimens include a loading dose of 50 to 100 mg either rectally or orally followed by a maintenance dose of 25 mg orally every 4 to 6 hours for 24 to 48 hours.[167]

Calcium-Channel Blockers

The calcium-channel blockers nifedipine and nicardipine inhibit preterm contractions by decreasing calcium influx into uterine smooth muscle and inhibiting myometrial contractions. No placebo-controlled trials have been performed with nifedipine, the most commonly used calcium-channel blocker. A meta-analysis of 12 randomized trials including a total of 1,029 women found that calcium-channel blockers were superior to other tocolytics (mostly β-mimetics) in reducing preterm births within 7 days and before 34 weeks' gestation.[169] A more recent study of 192 women comparing nifedipine with magnesium sulfate for preterm labor found no differences in delivery in 48 hours, gestational age at delivery, or deliveries before 32 or 37 weeks' gestation.[170] Maternal side effects were significantly fewer in patients receiving calcium-channel blockers compared with other tocolytics.[169,170]

Maternal side effects can include tachycardia, headache, flushing, dizziness, nausea, and hypotension in the hypovolemic patient.[164] Nifedipine does not adversely affect uteroplacental blood flow or fetal circulation. Concurrent use with magnesium should be avoided because the combination may potentiate neuromuscular blockade.[106,160,164] The starting dose is usually 10 mg PO with repeated doses of 10 mg every 15 to 20 minutes for persistent contractions, up to a maximum of 40 mg in the first hour.[172,173] Depending on the tocolytic effect, nifedipine is then maintained at 10 to 20 mg PO every 4 to 6 hours.[172] Overall, nifedipine appears to be an attractive alternative for short-term tocolysis because the drug is usually well tolerated.[174]

B.B. should be started on a magnesium sulfate 6-g IV loading dose for 30 minutes followed by 2 g/hour continuous IV infusion through a controlled infusion pump. The hourly rate of magnesium administration for B.B. may be increased until she has one or fewer contractions per 10 minutes or a maximum of 4 g/hour is attained. B.B.'s deep tendon reflexes, respiratory rate, and urine output should be monitored regularly. Close monitoring of fluid balance is important because fluid overload has been associated with pulmonary edema and the drug is renally excreted.[172]

Magnesium serum concentrations are commonly evaluated every 6 to 12 hours in an effort to minimize adverse effects.[175] The patellar reflex disappears with magnesium serum concentrations between 9 and 10 mg/dL, and as long as deep tendon reflexes are present, many practitioners will not measure concentrations. To prevent inadvertent overdoses, a controlled infusion device should always be used to deliver magnesium as a continuous infusion. Hypocalcemia and tetany can occur with hypermagnesemia. Neuromuscular blockade and respiratory arrest develop with magnesium serum concentrations of 15 to 17 mg/dL, and cardiac arrest develops with greater concentrations. The toxic effects of magnesium can be rapidly reversed with 1 g of parenteral calcium gluconate, which should be readily available when patients are receiving magnesium infusion.[164]

The most common side effects of magnesium loading doses are transient hypotension, flushing, a sense of warmth, headache, dizziness, lethargy, nystagmus, and dry mouth.[156,172] Other adverse effects reported with magnesium are hypothermia, paralytic ileus, and pulmonary edema, which may occur in 1% to 2% of patients treated with magnesium sulfate.[172] Pulmonary edema occurs less frequently with magnesium sulfate than with parenteral β-sympathomimetics but is more commonly encountered with prolonged infusions, multifetal pregnancy, and the use of multiple tocolytics.[164] Treatment consists of discontinuing magnesium sulfate and administration of the diuretic furosemide.

Fetal magnesium serum concentrations are similar to maternal concentrations.[172] The most common neonatal adverse effects are hypotonia and sleepiness. Hypotonia may continue for 3 or 4 days in the neonate because of decreased renal elimination of magnesium. Rarely, assisted mechanical ventilation for neuromuscular depression may be needed.[172]

DURATION OF TOCOLYSIS

Acute Therapy

CASE 49-7, QUESTION 5: B.B. has been maintained on magnesium sulfate continuous IV infusion for approximately 48 hours. The dose was increased to 3 g/hour shortly after the start of the infusion. B.B. has had no contractions for the past 24 hours. How long does she need to be treated? Should she be weaned off magnesium sulfate?

B.B.'s contractions have completely stopped for 24 hours. Some protocols maintain magnesium sulfate for 12 to 24 hours after successful tocolysis, or for the time it takes to complete the course of corticosteroids. The weaning of magnesium sulfate is unnecessary, and simple discontinuation of the magnesium infusion is an easier and less costly option.[174]

Chronic Maintenance Therapy

CASE 49-7, QUESTION 6: B.B. heard that preterm labor can return once stopped and asks whether she should stay on medication. Should B.B. be started on chronic maintenance tocolytic therapy?

Maintenance tocolysis has been used in an attempt to prevent recurrence of preterm labor and prolong gestation in women in whom preterm labor was terminated successfully with parenteral tocolytics. β-Adrenergics and oral calcium-channel blockers have been evaluated for maintenance therapy. Results of meta-analysis of trials comparing placebo or no treatment with oral β-adrenergics for maintenance therapy after acute preterm labor showed no benefit in delay of delivery, births at less than 34 or 37 weeks' gestation, or neonatal complications.[181] Moreover, increases in maternal adverse effects occurred, primarily tachycardia, hypotension, and palpitations. Lastly, inadequate data exist to support the use of calcium-channel blockers as maintenance therapy.[160] B.B. should not be started on chronic maintenance tocolysis, because there is not compelling evidence that continued suppression of contractions after acute tocolysis reduces the rate of preterm birth or neonatal morbidities.[155,159]

ANTENATAL GLUCOCORTICOID ADMINISTRATION

CASE 49-7, QUESTION 7: Given B.B. is in preterm labor at 29 weeks' gestation, what medication can be given to help facilitate fetal lung maturation?

B.B. should be given betamethasone 12 mg intramuscularly now and a second dose 24 hours later to facilitate fetal lung maturation by increasing production of fetal lung surfactant, thereby reducing the incidence and severity of RDS.[124] Antenatal corticosteroid administration (betamethasone and dexamethasone) also decreases the incidence of intraventricular hemorrhage, necrotizing enterocolitis, and neonatal death.[124] The greatest reduction in RDS occurs when delivery can be delayed 24 hours up to 7 days after starting treatment. Repeated weekly corticosteroid courses should not be given because of the association with decreased birth weight and head circumference, hypothalamic–pituitary–adrenal axis suppression, deleterious effects on cerebral myelination and lung growth, and neonatal death (particularly in neonates born to mothers who received three or more courses).[125,185] However, a randomized clinical trial has now demonstrated a significant reduction in neonatal respiratory morbidity and composite neonatal morbidity when women with preterm labor and intact membranes who had received an initial course of steroids at less than 30 weeks' gestation were treated again with a single rescue course of steroids (betamethansone 12 mg IM × 2 doses, 24 hours apart) if more than 2 weeks had passed and the gestational age was less than 33 weeks.[186] This rescue course was administered if there was judged to be a recurrent risk of preterm birth. Although long-term outcome data are not yet available, the ACOG now recommends consideration of a single rescue course of steroids under these specific circumstances.[125]

The National Institutes of Health (NIH) Consensus Panel and the ACOG recommend a course of antenatal betamethasone or dexamethasone (dexamethasone 4 mg IM × every 12 hours, for 4 doses) for all women in preterm labor between 24 and 34 weeks' gestation.[124,125] Betamethasone, however, might be the preferred agent because fewer IM injections are needed and because in meta-analysis it was associated with a greater reduction in RDS compared with dexamethasone.[185] That conclusion, however, is not based on direct comparison of betamethasone with dexamethasone and should be interpreted with caution. One study, although limited by its retrospective nature, also suggested an advantage of betamethasone over dexamethasone in the reduction of periventricular leukomalacia, a finding associated with later risks for cerebral palsy.[187] In cases of PPROM, the NIH Consensus Panel recommends that corticosteroids may be given up to 32 weeks' gestation in the absence of chorioamnionitis.[124,125] Recent meta-analysis supports the efficacy of corticosteroids in the reduction of neonatal death, RDS, duration of ventilator use, and intraventricular hemorrhage in infants born after ruptured membranes.[185] Women at more than 32 weeks' gestation can be considered for amniotic fluid testing for the presence of phosphatidylglycerol or a lecithin to sphingomyelin ratio of greater than 2 because these are indicators of fetal lung maturation.[185] Corticosteroids are not recommended for use in pregnant women who are at more than 34 weeks' gestation unless there is an indication of fetal lung immaturity (105, Neonatal Therapy).

Infectious Complications During Pregnancy and Labor

CASE 49-7, QUESTION 8: Preterm labor is often associated with an infectious etiology or source. Does B.B. need to be started on any antibiotic therapy because she is in preterm labor?

PRETERM PREMATURE RUPTURE OF MEMBRANES

Increasing evidence associates preterm labor with intra-amniotic infections.[152,186] Of preterm births, 20% to 40% may be caused by an infectious or inflammatory process.[156] Intrauterine infection is associated with approximately 80% of early preterm deliveries.[154] Most of the bacteria found in amniotic fluid and the placenta are believed to have ascended from the vagina.[156] It has been suggested that the microbes responsible for preterm birth are already present in the endometrium before conception or early in the pregnancy, causing a chronic, subclinical infection weeks to months before eventually causing PPROM or labor.[154,156]

When PPROM has occurred, spontaneous labor and delivery occurs on average within 7 days, although longer intervals from PPROM to delivery occur with earlier gestational ages.[187] The use of a short course of antibiotics has been shown to prolong the period between PPROM and delivery (the latency period) and decrease neonatal morbidity.[187] In the largest and best-designed trial of antibiotic treatment of PPROM, women between 24 and 32 weeks' gestation treated with ampicillin and erythromycin had both prolonged pregnancies and lower rates of chorioamnionitis.[188] Their newborns experienced decreased mortality, as well as decreased morbidity including RDS and necrotizing enterocolitis. These effects were not owing to tocolytics or corticosteroids because these were exclusionary factors. These results were confirmed by the results of a large meta-analysis including more

---

than 6,000 women, although information on the best choice of antibiotics was less clear.[189,190] Therefore, women with PPROM benefit from antibiotic therapy with a broad-spectrum regimen, and IV ampicillin plus erythromycin for 48 hours followed by 5 days of oral amoxicillin plus erythromycin for a total of 7 days treatment is a reasonable choice.[191]

B.B. should not be started on any PPROM antibiotic regimens because her membranes are not ruptured. Antibiotics have not been proved to prevent premature births in the setting of acute preterm labor.[158] There is currently no role for antibiotic use to prolong pregnancy or reduce neonatal morbidity in preterm labor with intact membranes, and it may be associated with long-term harm.[158,192] There may be a role for treatment of bacterial vaginosis antenatally to reduce the risk of preterm birth in women with a past history of spontaneous preterm birth.

BACTERIAL VAGINOSIS

Some, but not all, studies have demonstrated that screening and treating asymptomatic women who are at high risk for preterm delivery for bacterial vaginosis (BV) may reduce the risk of preterm birth.[158,160] A polymicrobial overgrowth of mostly anaerobic bacteria, BV, is one of the most common genital infections in pregnancy, and it is associated with an increased risk of preterm delivery.[193] Treatment of women with BV who had a prior preterm delivery with oral metronidazole in combination with erythromycin decreased the risk of recurrent preterm delivery in one randomized clinical trial, but there was no difference for women without a history of recurrent preterm birth.[197,198] In addition, a meta-analysis including 622 women with prior preterm birth found no reduction in the risk of preterm birth before 37 weeks' gestation after treatment of BV with antibiotics, but did find a reduction in PPROM. In addition, in women with BV who were treated with oral antibiotics before 20 weeks' gestation, there was a reduction in preterm birth at less than 37 weeks.[198] B.B. does not have BV; therefore, treatment with metronidazole is unnecessary.

GROUP B STREPTOCOCCUS INTRAPARTUM PROPHYLAXIS

Antibiotics should be given to women if delivery is anticipated resulting either from preterm labor with intact membranes or after PPROM to prevent group B streptococcal (GBS) infection in the newborn. Other broad-spectrum antibiotic therapy to prevent preterm delivery should not be given routinely to women in preterm labor with intact membranes.

Approximately 10% to 30% of pregnant women are colonized with GBS or Streptococcus agalactiae in the vagina or rectum, and 1% to 2% of neonates born to colonized women experience early-onset invasive GBS disease in the absence of IV intrapartum antibiotic prophylaxis.[199] One-fourth of all cases of neonatal GBS infections occur in preterm newborns. B.B.'s fetus, therefore, is at risk for invasive GBS infection from vertical transmission (mother to infant) of bacteria during labor or delivery. The mortality rate for GBS is reported to be between 5% and 20%. Fortunately, the incidence of GBS has declined to a rate of 0.34 to 0.37 cases per 1,000 live births in recent years owing to prevention efforts.[199] During pregnancy, GBS infection can cause maternal urinary tract infection, amnionitis, endometritis, and wound infection. Antibiotics given to the mother during preterm labor and delivery help to prevent neonatal GBS disease, which may lead to sepsis, pneumonia, and meningitis. In the past decade, the routine administration of intrapartum antibiotic prophylaxis to certain subsets of pregnant women has led to a 70% reduction in the overall incidence of GBS disease.[199] The decision to treat women with intrapartum antibiotics has been based on either a positive vaginal and rectal GBS culture routinely obtained at 35 to 37 weeks' gestation or one or more of the following risk factors without culture screening: (a) previous infant with invasive GBS disease; (b) GBS bacteriuria during any trimester of the current pregnancy; (c) unknown GBS status at onset of labor and any of the following: delivery at less than 37 weeks' gestation, amniotic membrane rupture at 18 hours or more, intrapartum temperature of 38°C (100.4°F) or greater.[199]

Vaginal and rectal GBS cultures should be obtained from B.B., and she should be given a loading dose of penicillin G injection 5 million units, followed by 2.5 to 3.0 million units IV every 4 hours until delivery, while awaiting success of tocolysis and culture results. The Centers for Disease Control and Prevention guidelines recommend that the benchmark for optimal prophylaxis should be antibiotics given at least 4 or more hours before delivery. Penicillin G is preferred over ampicillin because it has a narrower spectrum of antimicrobial activity. If B.B. had a severe allergy to penicillin, sensitivities to clindamycin and erythromycin should be requested at the time of culture in the event GBS is found because of increasing resistance to these drugs. If the isolate is susceptible to both clindamycin and erythromycin, then clindamycin 900 mg IV every 8 hours should be used until delivery. Erythromycin is no longer recommended as an option for treatment because it is often associated with inducible resistance to clindamycin. If the isolate is not susceptible to both clindamycin and erythromycin or if sensitivities are not available, penicillin-allergic women at high risk for anaphylaxis should receive vancomycin 1 g IV every 12 hours until delivery. Penicillin-allergic women at low risk for anaphylaxis should receive cefazolin 2 g IV initially, then 1 g IV every 8 hours until delivery.[192,193] Because B.B is only at 29 weeks' gestation and is in preterm labor, she has not yet had her GBS culture obtained, which normally occurs at 35 to 37 weeks. Until the results of her rapid testing for GBS culture returns, she should receive penicillin G, 3 million units IV every 4 hours until delivery to prevent perinatal GBS infection

CASE 49-7, QUESTION 9: B.B.'s culture results are negative for GBS growth. She is still at high risk for imminent delivery. Should penicillin G administration be discontinued?

Penicillin should be discontinued at this time. Vaginal and rectal cultures need not be repeated if B.B. delivers within the next 4 weeks. If tocolysis is successful and delivery is delayed for more than 4 weeks, obtaining cultures and starting penicillin G preemptively should be repeated at that time. Intrapartum prophylaxis is effective only if antibiotics can be given immediately before and during delivery.

CASE 49-7, QUESTION 10: B.B.'s contractions are gone, and her cervical examination remains unchanged for 48 hours. She is able to be discharged home undelivered, but is counseled to stay on bed rest for the duration of the pregnancy. B.B. has a significant history of a prior preterm delivery at 32 weeks' gestation. What medication should be recommended to B.B. now and in her next pregnancy, to decrease her risk and prevent another preterm delivery from occurring?

Recent studies have shown that progesterone supplementation can help to reduce preterm births, but should only be used in women who have had a prior documented history of a spontaneous preterm birth before 37 weeks' gestation.[194] The optimal progesterone product is not known (vaginal suppositories, oral capsules, or IM injectables). Progesterone should be offered to women like B.B. who have had a prior history of spontaneous preterm delivery.[200] A recent randomized, double-blinded, placebo-controlled trial found a significant reduction in the rate of preterm deliveries in these high-risk women with a prior documented history of preterm delivery with the use of 17-α hydroxyprogesterone (17-OHP).[195] The rate of preterm delivery in the treatment group was 6.3% versus 54.9% in the placebo group.[195] 17-OHP is given as an IM injection prepared as 250 mg/mL once weekly. Therapy should be initiated at 16 to 20 weeks' gestation and continued until 37 weeks' gestation.[195] 17-OHP is widely available from compounding pharmacies, and most recently, a commercially marketed FDA-approved drug called Makena has been released into the market.[196] Although B.B. is already 29 weeks pregnant, she should be started on 17-OHP therapy at 250 mg/mL injected IM once weekly until 37 weeks. She should be counseled that progesterone should be started earlier at 16 weeks in her next pregnancies. The compounded 17-OHP is more affordable, cost-effective, and equally as effective as the marketed Makena product.[196]

Chorioamnionitis

CASE 49-7, QUESTION 11: B.B. returns to labor and delivery at 36 5/7 weeks' gestation with spontaneous rupture of the membranes and is found to be 4 cm dilated and 80% effaced. Her vital signs currently are a BP of 106/79 mm Hg, heart rate of 80 beats/minute, and respiratory rate of 12 breaths/minute with 99% oxygenation on room air. Intrapartum fetal monitoring shows a reassuring reactive fetal heart rate with variability. After being in labor for about 16 hours, her temperature spikes up to 101.1°F. What are the risks of an elevated fever during labor, and how should B.B. be treated?

Chorioamnionitis is an infection of the amniotic fluid, membranes, and placenta occurring before, during, or immediately after birth.[197] Intra-amniotic infections occur in approximately 1% to 5% of term pregnancies and may complicate up to 15% of cases of preterm labor.[204] Maternal fevers are usually the most common clinical presentation in many patients. Diagnosis is based on the presence of fever, defined as 100.4°F (38°C) or greater measured twice at least 4 hours apart, or a temperature of 101°F (38.3°C) measured once. Patients may also present with maternal tachycardia (>100 beats/minute), fetal tachycardia (160 beats/minute), uterine tenderness, foul odor from amniotic fluid, and maternal leukocytosis.[197,198] The exclusion of other sources of infection such as urinary tract infection, viral illness, abscesses, and drug-induced fever (i.e., epidural, misoprostol) must be made. Common organisms ascending from vaginal flora causing polymicrobial intra-amniotic infections include genital mycoplasmas such as U. urealyticum and Mycoplasma hominis, anaerobes including G. vaginalis, enteric gram-negative bacilli, and GBS.[198,199] The two most prominent risk factors of intra-amniotic infections are the number of digital examinations and duration of labor.[197]

Maternal complications from intra-amniotic infections include bacteremia, suboptimal uterine contractility, and risk for postpartum hemorrhage.[198] Increases in rates of neonatal sepsis, pneumonia, meningitis, and mortality have been shown in infants whose mothers had chorioamnionitis.[200] Furthermore, inflammation, intrapartum fever, and infection increase the risk of long-term neurodevelopmental delay and cerebral palsy in these neonates.[201] The risk of cerebral palsy is at least twofold to fourfold higher in infants who were exposed to intra-amniotic infection in utero.[201]

Early administration of broad-spectrum antibiotics immediately after the diagnosis of chorioamnionitis has been shown to have both maternal and neonatal benefit versus postpartum antibiotic administration. A common regimen implemented is ampicillin 2 g IV every 6 hours in addition to gentamicin dosed to a target peak of 8 mcg/mL and trough of 1 mcg/mL.[198] Standard dosing of gentamicin dosed every 8 hours is preferred over once-daily dosing to prevent elevated fetal serum peak levels, although no adverse effects of high-dose therapy were noted.[202] Clindamycin 900 mg IV every 8 hours may be added to the regimen to cover anaerobic organisms. If fevers persist for longer than 24 hours on triple antibiotics with ampicillin, gentamicin, and clindamycin, metronidazole can be substituted for clindamycin to help broaden anaerobic coverage.[198] Other options for antibiotic coverage include extended-spectrum penicillins (i.e., piperacillin–tazobactam, ampicillin–sulbactam) or second-generation cephalosporins (i.e., cefoxitin and cefotetan).[198] Intrapartum antibiotics administered about 1 hour after infusion produce adequate bactericidal concentrations in the fetus and placental membranes.

With a fever of 101.1°F, B.B. meets criteria for a clinical diagnosis of chorioamnionitis. However, she does not exhibit any other symptoms of systemic infection such as tachycardia, uterine tenderness, or fetal tachycardia, which is quite common. Gentamicin and ampicillin should be started promptly after diagnosis to decrease the risk of neonatal sepsis and to avoid possible neurodevelopment sequelae. In addition, clindamycin can be added to cover anaerobic organisms. B.B.'s risk for chorioamnionitis includes multiple digital examinations, preterm labor, spontaneous labor, and long duration of labor. Antibiotics should be continued until B.B. is afebrile for at least 24 to 48 hours or until delivery. Ultimately, immediate antibiotic administration and delivery of the offending source is paramount to ensure fetal health and safety.

Human Immunodeficiency Virus in Labor and Breast-Feeding

CASE 49-8

QUESTION 1: S.L. is a 23-year-old G1, P0 at 38 weeks' gestation and is positive for HIV. She is presenting to labor and delivery with spontaneous rupture of membranes and is having regular contractions every 5 minutes. Her last HIV RNA levels were undetectable, and her CD4 count was 400 cells/μL. Her current combination antiretroviral therapy (cART) consists of zidovudine (AZT), lamivudine, and atazanavir/ritonavir, which was started 2 years ago. What are the risks of HIV perinatal transmission in S.L., and what medications must be started while she is in labor?

Current recommendations state that all HIV-infected pregnant women should receive intrapartum AZT if the HIV RNA level is >1,000 copies/mL, and their infants should receive neonatal AZT immediately after delivery for 6 weeks with a consideration for a 4 week treatment plan if the mother has been maintained on a cART regimen thought out the pregnancy.[203] Many factors must be taken into consideration, including cost, ease of administration for compliance, individual ART resistance patterns, and risks of side effects with the possibility of teratogenicity.[204] Generally, if a woman on cART becomes pregnant, she should continue on therapy throughout the pregnancy, including the first trimester.[203] Women who did not require cART before becoming pregnant should start cART prophylaxis after the first trimester but not later than 28 weeks of gestation.[203] cART is more effective in preventing perinatal HIV transmission if it is started earlier, before 28 weeks' gestation versus 36 weeks' gestation.[203] All HIV-infected women should be counseled and offered cART during pregnancy to prevent perinatal transmission regardless of HIV RNA levels.[203] Avoid the use of stavudine and didanosine entry and fusion inhibitors in women of childbearing age and during the first trimester, if possible due to issues of toxicity and teratogenicity.[203] Efavirenz in the updated guidelines can be continued to be used if the women was on a efavirenz based regimen. A fetal ultra sound is recommended. Further studies are needed to help identify the effectiveness and safety of other cART regimens. Cesarean section delivery is highly recommended.[203]

S.L. should continue on her ART (AZT, lamivudine, and atazanavir/ritonavir) during labor without missing any doses. Prophylactic neonatal AZT should be administered to the infant at a dose of 4 mg/kg (actual weight) PO every 12 hours, within 6 to 12 hours of birth, for a total duration of 6 weeks.[203]

CASE 49-8, QUESTION 2: Should S.L. breast-feed her infant if her HIV RNA levels are undetectable and her CD4 counts are 400 cells/μL?

Although S.L. is currently on effective cART to suppress her HIV RNA levels and maintain her CD4 levels, she should not breast-feed. Breast-feeding is not recommended for HIV-infected women in the United States because of safer and affordable alternatives such as formula. Prophylactic cART in the infant and mother does not entirely eliminate the risk of perinatal transmission through breast milk.[203]

POSTPARTUM HEMORRHAGE

Prevention

CASE 49-8, QUESTION 3: S.L. successfully has a normal spontaneous vaginal delivery with an estimated blood loss of 400 mL. Which medications should be given to S.L. routinely after delivery?

Oxytocin is administered routinely after the delivery of the placenta to promote uterine contraction and vasoconstriction. Meta-analysis of randomized clinical trials demonstrates that the use of oxytocin preventively in the third stage of labor reduces the risk of hemorrhage and need for medical therapy for uterine atony.[205] Uterine atony, the condition in which the uterus fails to contract after delivery of the placenta, is the most common cause of postpartum hemorrhage.[206] Risks for uterine atony include induction and augmentation of labor, prolonged labor, an overdistended uterus such as with twins or polyhydramnios, and previous postpartum hemorrhage.[206] Oxytocin 10 to 20 units IM or diluted in 0.5 to 1 L of parenteral fluid and given as an IV infusion of 200 milliunits/minute until the uterus is firmly contracted reduces the risk for postpartum hemorrhage secondary to uterine atony.[207] Oxytocin should never be administered undiluted as a bolus dose because it can cause severe hypotension and cardiac dysrhythmias.[207]

MISOPROSTOL

Misoprostol 400 to 600 mcg can be administered orally in the third stage of labor to prevent postpartum hemorrhage.[208,209] In a comparison of 600 mcg of oral misoprostol with parenteral oxytocin for prevention of postpartum hemorrhage, oxytocin was marginally but statistically more effective and had fewer side effects.[210] Misoprostol also can be administered rectally. Rectal administration is associated with a lower incidence of fever and shivering, which is common with orally administered misoprostol during the third stage of labor.[210] The rectal route of administration also is associated with lower maximal serum concentrations and lower time to maximal concentrations than when the drug is administered orally. Although not as effective as oxytocin in preventing postpartum hemorrhage, misoprostol, which is inexpensive, stable at room temperature, and not administered parenterally, may be preferred in settings of meager resources for management of the third stage of labor.

S.L. should receive an infusion of oxytocin 20 units in 1 L of lactated Ringer solution at 125 mL/hour.

Treatment

CASE 49-8, QUESTION 4: Within a few hours of delivering her baby, S.L. has visible vaginal bleeding. She has a distended uterus, and the hemorrhage is attributed to uterine atony. Uterine massage, which is standard treatment, does not control the bleeding. What other pharmacologic options are available to treat her postpartum hemorrhage in addition to the infusion of more oxytocin at this time?

ERGOT ALKALOIDS

If the postpartum hemorrhaging does not respond to oxytocin administration, ergonovine maleate (Ergotrate) and its semisynthetic derivative, methylergonovine maleate (Methergine), can be used because of their potent uterotonic effects. IM administration is associated with less frequent adverse effects (nausea, vomiting, hypertension, headache, chest pain, dizziness, tinnitus, diaphoresis) than the IV route.[207] Ergot alkaloids should be avoided in hypertensive and eclamptic patients because of the potential for arrhythmias, seizures, cerebrovascular accidents, and rarely myocardial infarction. The dose of both drugs is 0.2 mg administered IM every 2 hours as needed. This may be followed by 0.2 to 0.4 mg administered PO 2 to 4 times daily for 2 to 7 days to promote involution of the uterus (Table 49-5).[207]

15-METHYL PROSTAGLANDIN F_{2a} (CARBOPROST TROMETHAMINE)

Bleeding caused by uterine atony that is unresponsive to oxytocin can be treated with 15-methyl prostaglandin $F_{2\alpha}$-tromethamine, also known as carboprost tromethamine (Hemabate).[206] Carboprost tromethamine, as with naturally occurring prostaglandins, stimulates uterine contraction and decreases postpartum hemorrhage; it is more potent and has a longer duration of effect than its parent compound, prostaglandin $F_{2\alpha}$.

Table 49-5

Uterotonic Medications Used for Postpartum Obstetric Hemorrhage

Drug	Dose	Comments
Oxytocin (Pitocin)	40 IU in 1 L NS or lactated Ringer solution	Do not give as undiluted IV bolus, can cause hypotension

	10 IU IM if no IV site available	
Methylergonovine maleate (Methergine)	0.2 mg IM every 2–4 hours	Contraindicated in hypertensive patients
Carboprost tromethamine (Hemabate)	0.25 mg IM every 15–90 minutes, not to exceed eight doses	Caution in use with patients with asthma, can cause bronchoconstriction
Misoprostol	1,000 mcg rectally given once	Can be also be given orally or sublingually, but PR is preferred route

IM, intramuscular; IV, intravenous; NS, normal saline; PR, per rectum.

Source: Cunningham FG et al. Obstetrical hemorrhage. In: Gary Cunningham F et al, eds. Williams Obstetrics. 24th ed. New York, NY: McGraw-Hill; 2014

Carboprost tromethamine is approved for IM use, but also has been also administered through direct myometrial injection.[207,211] Intramyometrial administration has been associated with severe hypotension and pulmonary edema.[212] An initial dose of 0.25 mg IM is given followed by 0.25 mg every 15 to 90 minutes.[207,211] The total cumulative dose should not exceed 2 mg (eight doses maximum).[211] Carboprost tromethamine is effective in treating 60% to 85% of women with uterine atony who have failed standard treatment.[207] Improvement in bleeding typically occurs after one to two injections.

The most common adverse effects of carboprost tromethamine are GI, including nausea, vomiting, and diarrhea. Flushing and fever also occur frequently. Many of the adverse effects are related to the contractile effect of this drug on smooth muscle.[211] Hypertension, although rare, typically occurs in women with preexisting hypertension or preeclampsia. The potent vasoconstricting and bronchoconstricting properties of carboprost can cause uterine rupture, as well as pulmonary and cardiac problems. Carboprost must be used with caution in women with asthma and is relatively contraindicated in the presence of pulmonary, cardiac, renal, or hepatic disease.[206,211]

MISOPROSTOL

Several case series and small randomized trials have reported that misoprostol might be useful in the treatment of postpartum hemorrhage caused by uterine atony. The available data are very limited, however, and large randomized trials are needed to clarify the efficacy of misoprostol compared with standard therapies, as well as the optimal dose and route of administration.[213] A recent double-blind, randomized, placebo-controlled clinical trial was performed to clarify the role of misoprostol for the treatment of postpartum hemorrhage.[214] Treatment was either 800 mcg of sublingual misoprostol or 40 IU of oxytocin in 1 L of IV fluid given for 15 minutes. Resolution of active bleeding occurred within 20 minutes in 89% to 90% of women in each study arm, demonstrating no advantage to misoprostol over standard IV therapy with oxytocin. Furthermore, women who received misoprostol had significantly more shivering and fever greater than 40°C. In areas with meager resources, misoprostol may offer advantages (low cost, prolonged stability, and oral formulation), but the role for misoprostol as an adjunctive therapy when oxytocin is already available remains uncertain.[207]

S.L. does not have any contraindications (i.e., asthma or hypertension) to any of the postpartum hemorrhage medications. She should be given oxytocin 40 IU in 1 L of lactated Ringer solution given for 15 minutes. Methylergonovine maleate 0.2 mg IM and misoprostol 1,000 mcg rectally can be given in succession after oxytocin if bleeding does not subside. Lastly, carboprost tromethamine 0.25 mg IM is an option if those medications fail to control bleeding.

PREVENTION OF RH D ALLOIMMUNIZATION

Maternal–Fetal Rh Incompatibility

CASE 49-9

QUESTION 1: G.G., a 34-year-old primigravida, had her ABO blood group and Rh status determined during her initial prenatal visit. She is found to be type O, Rh negative. Her husband is type O, Rh positive. What are the risks associated with Rh incompatibility that could affect G.G.'s unborn?

Blood group incompatibility between a pregnant woman and her fetus can result in alloimmunization of the mother and hemolytic anemia in the fetus. When a woman is exposed during pregnancy, labor, or delivery to an antigen found on the fetus's red blood cells (i.e., AB, Rh complex) that is not found on her own red blood cells (RBCs), she forms antibodies against fetus's antigen. This is referred to as alloimmunization. These antibodies, particularly immunoglobulin (Ig) G antibodies, cross the placenta and can interact with the fetal RBC antigens. The pregnancy in which the alloimmunization has occurred usually results in an unaffected child. The risk is carried on in subsequent pregnancies when maternal antibodies from a tiny amount of blood (less than 0.1 mL) can cross from the mother to child, which can result in the destruction of RBCs and lead to hemolytic disease of the newborn (HDN). Most serious cases of HDN are caused by Rh alloimmunization involving the D antigen. The other four alleles of the Rh gene complex code for the antigens C, c, E, and e. They are also serious, but less common, causes of alloimmunization.[215]

An Rh D-negative mother becomes immunized after exposure to fetal erythrocytes that carry the D antigen. The likelihood of having an Rh D-positive offspring is determined by whether an Rh D-positive father is homozygous or heterozygous for the D antigen. If the father is homozygous for the D antigen, all of his offspring will be D positive (Rh positive). If he is heterozygous for the D antigen, then there is a

50% chance that his offspring will be Rh positive.

Pregnant women can produce detectable IgG antibodies to Rh antigens within 6 weeks to 6 months.[216] These antibodies can cross the placenta during subsequent pregnancies and destroy fetal Rh D-positive RBCs. Of Rh D-negative women who do not receive Rh_o(D) immune globulin during pregnancy, 17% will become alloimmunized during a term pregnancy, with most cases occurring at the time of delivery.[217]

The severity of Rh-associated HDN or erythroblastosis fetalis depends on the concentration of maternal antibodies. The placental transfer of large amounts of antibody can cause substantial RBC destruction. This initially results in anemia and hyperbilirubinemia with compensatory extramedullary erythropoiesis (e.g., liver, spleen). In severe hemolytic diseases, the fetus might develop hepatosplenomegaly, portal hypertension, edema, ascites, and hepatic and cardiac failure. The clinical presentation of profound anemia, anasarca, hepatosplenomegaly, cardiac failure, and circulatory collapse is termed hydrops fetalis.[216]

The severity of Rh-associated HDN generally worsens with each pregnancy in the alloimmunized mother if her fetus is Rh positive. Thus, it is important to discuss the consequences of alloimmunization with any woman who is known to be alloimmunized and wishes to have more children in the future.[217]

Rh_o(D) Immunoglobulin

CASE 49-9, QUESTION 2: What interventions should be undertaken to prevent G.G. from becoming alloimmunized?

ANTEPARTUM PROPHYLAXIS

G.G. should have antibody screens at the beginning of each pregnancy and postpartum. Although the American Association of Blood Banks recommends that an antepartum screen should also be obtained at 28 weeks' gestation, the cost-effectiveness of such screening has not been studied, and it is estimated that sensitization before 28 weeks occurs at a rate of less than 0.18%. Therefore, the ACOG has suggested that the decision to obtain a third-trimester antibody screen should be dictated by individual circumstances.[217] As pregnancy progresses, both the incidence and the degree of fetomaternal hemorrhage increase.

Administrating Rh_o(D) immune globulin to G.G. before or shortly after exposure to fetal Rh D-positive RBCs will prevent her from becoming alloimmunized. Giving Rh_o(D) immune globulin at 28 weeks' gestation has been shown to decrease the antepartum sensitization rate from approximately 2% to 0.1%.[217] One mechanism by which $Rh_o(D)$ immune globulin might prevent sensitization is by suppression of the primary immune response to the D antigen.[216] The anti-D immune globulin binds the D antigen, and this complex is filtered by the spleen and lymph nodes whereby it inhibits D antigen-specific B cells from proliferating.

POSTPARTUM PROPHYLAXIS

A second dose of $Rh_o(D)$ immune globulin should be repeated within 72 hours of delivery. A larger dose is needed if a large transplacental bleed occurs at the time of delivery (0.4% of cases). Therefore, all $Rh_o(D)$-negative women who deliver an $Rh_o(D)$-positive newborn should be tested to detect fetal RBCs in maternal blood (e.g., Kleihauer–Betke test) to calculate the correct dose of $Rh_o(D)$ immune globulin. If a woman at risk for sensitization has not been given $Rh_o(D)$ immune globulin within 72 hours, she should still be treated as soon as possible because it has been demonstrated that protection can be seen in some individuals up to 13 days after exposure to Rh-positive RBCs.[217]

ADVERSE EFFECTS OF $RH_O(D)$ IMMUNE GLOBULIN

The plasma from which immune globulin is obtained is tested for viral infections, and the manufacturing process used to produce $Rh_o(D)$ immune globulin inactivates viruses such as HIV, hepatitis B virus, and hepatitis C virus.[218] Adverse reactions associated with the use of anti-D immune globulin are rare. Pain and swelling at the injection site and rash are the most common adverse reactions. Hypersensitivity reactions such as anaphylaxis, although rare, can occur owing to a small amount of IgA in the product. $Rh_o(D)$ immune globulin (RhoGAM) is latex-free and thimerosal-free (contains no mercury).[218]

Prophylaxis for First- and Second-Trimester Events and Procedures

CASE 49-9, QUESTION 3: G.G. will undergo amniocentesis at 16 weeks' gestation. Will she need a dose of $Rh_O(D)$ at that time?

$Rh_o(D)$ immune globulin should be given after all clinical events (e.g., spontaneous abortion) or procedures (e.g., abortion, amniocentesis, fetal blood sampling, or chorionic villus sampling) in which fetomaternal hemorrhage is a risk in an Rh-incompatible pregnancy.[218]Although little evidence supports the need for prophylaxis in the early first trimester, adverse effects are rare and potential benefits are thought by most experts to outweigh the risks.[217,218] Although a 50-mcg dose

(MICRhoGAM) is available for first-trimester use (e.g., chorionic villus sampling or abortion), many hospitals do not stock this dose and so a 300-mcg standard dose is often given.

LENGTH OF PROTECTION

CASE 49-9, QUESTION 4: G.G. had an amniocentesis at 16 weeks for which she received Rh_o(D) immune globulin 300 mcg IM. Will she need another dose at 28 weeks' gestation? How long will this dose protect G.G. against alloimmunization?

G.G. will still need a dose of 300 mcg repeated at 28 weeks' gestation and within 72 hours postpartum if her infant is Rh_o(D)-positive. The half-life of Rh_o(D) immune globulin is approximately 23 to 26 days.[218] Without a large fetomaternal hemorrhage, a standard dose of 300 mcg will protect against alloimmunization for up to 12 weeks. If more than 12 weeks have lapsed between receipt of anti-D immune globulin and delivery, many practitioners recommend administering another antepartum dose.[217,218]

Failure of Immunoprophylaxis

CASE 49-9, QUESTION 5: What are the most common reasons for Rh D alloimmunization during pregnancy?

The most common reasons for Rh D alloimmunization are (a) failure to give a dose of anti-D immune globulin at 28 weeks' gestation, (b) failure to give Rh_o(D) immune globulin in a timely manner postpartum to women who have delivered an Rh_o(D)-positive or untyped fetus, and (c) failure to recognize clinical procedures and situations that increase maternal risk for alloimmunization (i.e., amniocentesis, abortions).[216,217]

Thus, G.G. should be told that with proper prophylaxis with anti-D immune globulin, there is little chance for her to become alloimmunized. She need not worry about her present pregnancy or future pregnancies.

LACTATION

Lactation is controlled primarily by prolactin (PRL), but the entire process is under the intricate control of several hormones. Breast tissue maturation during pregnancy is influenced by many factors, including estrogen, progesterone, PRL, insulin, growth hormone, cortisol, thyroxine, and human placental lactogen.[219] PRL concentrations gradually increase during pregnancy, but high estrogen and progesterone concentrations inhibit milk secretion by blocking PRL's effect on the breast epithelium.[219,220] It is the dramatic decrease in progesterone that triggers lactogenesis or milk secretion for the first 3 days after delivery. Infant suckling at the breast is necessary to maintain an adequate milk supply beyond postpartum day 3 or 4. Nipple stimulation transmits sensory impulses to the hypothalamus to initiate PRL release from the anterior pituitary and oxytocin from the posterior pituitary. PRL stimulates the production and secretion of breast milk, and oxytocin stimulates the contraction of the myoepithelial cells in the breast alveoli and ducts so that milk can be ejected from the breast (milk letdown). Oxytocin also can be secreted through other sensory pathways, which is why women can release milk on hearing, smelling, or even thinking about their infants. PRL, however, is released only in response to nipple stimulation.

PRL synthesis and release depend on the inhibition of hypothalamic prolactin inhibitory factor (PIF) secretion. PRL secretion is regulated primarily by dopamine-releasing neurons. Activating the dopamine receptors on the PRL-secreting cells of the anterior pituitary inhibits the release of PRL. PIF is believed to be closely associated with dopamine.[219,220]

Although PRL controls the volume of milk produced, once lactation is established, milk production is regulated by infant demand. Lactation eventually ceases if milk is not removed from the breast. Absence of suckling stops milk letdown and restores the normal production of PIF. Decreased blood flow to the breast reduces oxytocin delivery to the myoepithelium. Consequently, milk secretion stops within a few days.[219,220]

Stimulation

NONPHARMACOLOGIC MEASURES

CASE 49-10

QUESTION 1: C.C., a 22-year-old woman, vaginally delivered her first child, a healthy term infant. C.C. plans to breast-feed and was educated about breast-feeding during obstetric visits and prenatal classes. After giving birth, C.C. tried to breast-feed in the delivery room with great difficulty. Afterward, she became extremely apprehensive and continued to have trouble breast-feeding. What can be done to encourage C.C. and help her with lactation?

The most effective stimulus for lactation is suckling. Many women nurse in the delivery room after uncomplicated vaginal deliveries because nursing increases maternal–infant bonding and helps establish good milk production. If a mother does not nurse immediately after delivery, she should be encouraged to do so as soon as she is physically able. C.C. did try to nurse after delivery, but experienced problems that may have been related to her emotional or physical state, or to the physical state of her infant. The nursing staff should encourage and support C.C. emotionally to help her relax, be comfortable, and relieve her anxiety about breast-feeding. Healthcare personnel also should emphasize appropriate feeding techniques and proper positioning for breast-feeding. Allowing C.C.'s infant to sleep in her room, rather than the nursery, may help C.C. develop a breast-feeding routine.

Most new mothers who have difficulty breast-feeding initially respond to the emotional and educational support of a good obstetric nursing staff. Few require pharmaceutical intervention.

ENHANCEMENT OF MILK PRODUCTION

CASE 49-10, QUESTION 2: C.C. was successful in establishing breast-feeding. Despite good technique and adequate nutrition, however, she had trouble maintaining adequate milk production after about 2 to 3 weeks and was forced to supplement her infant with formula. How can C.C.'s milk production be enhanced?

Although not an FDA-approved indication, metoclopramide can be used to stimulate lactation in women with decreased or inadequate milk production.[38, 221–223] Metoclopramide, a dopamine antagonist, increases PRL secretion. This is particularly useful in women whose infants do not breast-feed effectively (e.g., preterm infants).[224] Metoclopramide 10 mg PO 3 times daily for 1 to 2 weeks has been shown to help restore milk production.[38,221–223] Improvement in lactation occurs within 2 to 5 days of starting therapy and persists after discontinuing metoclopramide.

The estimated total daily dose of metoclopramide ingested by the nursing infant of a woman on 30 mg/day is 1 to 45 mcg/kg/day.[38] This is below the maximal recommended infant daily dose of 0.5 mg/kg/day. Maternal doses of 30 mg/day do not alter PRL, thyroid-stimulating hormone, or free thyroxin serum concentrations in breast-fed infants.[224] The only adverse effect reported in nursing infants has been intestinal gas.[38,225] The short-term use of metoclopramide for re-establishing lactation appears to be safe, even in preterm infants.[38,221]

Recent randomized control trials have examined the effects of metoclopramide on breast milk volume and duration in women with recent preterm deliveries and found that breast-feeding outcomes were poor despite medication treatment and lactation support.[225,226] In this special population, women likely need lactation support through various resources addressing nutritional, medical, and psychosocial interventions.

Suppression

CASE 49-11

QUESTION 1: After delivery of a nonviable fetus at 24 weeks' gestation, J.G., a 26-year-old G2, P2, informs her obstetrician that she wishes to suppress her lactation. What methods are available to suppress lactation?

Suppression of lactation is indicated for women who do not want to breast-feed, women who have delivered a stillborn infant, and those who have had an abortion. Both drugs and nonpharmacologic methods have been used. In 1988, the FDA, however, recommended against drug-induced suppression of lactation.[227] The only drug therapy that the FDA recommends in women who are not breast-feeding is analgesic for the relief of breast pain. Bromocriptine was approved for the postpartum suppression of lactation; however, the FDA rescinded its approval for that indication because of cardiovascular complications (e.g., stroke, myocardial infarction) associated with its use.[220]

If breast stimulation is avoided (with or without the use of a breast binder), breast milk production will continue, leading to engorgement and distension of breast alveoli. This leads to the termination of lactation after several days. Approximately 40% of women using this method experience breast discomfort and pain; 30% experience milk leakage from their nipples.[227,228] Ice packs may be applied to the breasts for comfort, and a mild analgesic may be used if necessary.

DRUG EXCRETION IN HUMAN MILK

Breast milk is recognized as the optimal source of nutrition for infants, with documented benefits not only to infants, but also to mothers, families, and societies.[229] Evidence indicates that breast-feeding decreases the incidence or severity of many infectious processes (e.g., otitis media, respiratory infections, urinary tract infections) in infants. In children and adults who were breast-fed, the risk of developing certain medical illnesses also may decrease (e.g., obesity, inflammatory bowel disease, celiac disease, childhood leukemia).[230] Breast-feeding may also positively influence cognitive and intellectual development in children and young adults.[231] Numerous benefits to the mother also have been identified, such as decreased postpartum blood loss, more rapid uterine involution, earlier return to prepregnancy weight, and decreased risks of breast cancer, ovarian cancer, and osteoporosis.[229]

The perception that nursing should be discontinued while the mother is medicated persists, although only a finite number of drugs are absolutely contraindicated during lactation.[95] Unlike the use of drugs during pregnancy, drug excretion in breast milk can be approximated to a certain extent. Actual measurements of drug concentrations in milk and clinical observations in breast-fed infants have been published for selected drugs.

Pharmacokinetics

Different pharmacokinetic models of drug excretion in milk have been described.[233] A two-compartment open model presents the maternal fluids as one compartment and breast milk as the other. After ingestion, the drug gets absorbed into the maternal compartment, with a proportion of drug passing into breast milk and the remaining portion distributed in, and eliminated from, the maternal system. Drugs reaching breast milk will ultimately leave this compartment either by diffusing back into maternal fluids or through milk production and nursing.[232] A more popular model describes drug excretion in milk using a three-compartment model that incorporates the pharmacokinetics of the mother, mammary tissues, and infant.[234] The overall risk to the infant depends on the amount of drug bioavailable to the mother, the amount reaching breast milk, and the actual amount of drug ingested and bioavailable to the nursing infant.

Transfer of Drugs From Plasma to Milk

Transfer of drugs from maternal plasma to milk is generally through passive diffusion.[233] Low-molecular-weight, water-soluble substances diffuse through small, water-filled pores, whereas lipid-soluble compounds pass through lipid membranes.[232] Many factors affect the excretion of drugs in breast milk, and they should be carefully assessed before making a recommendation. The extent of drug passage into breast milk is often expressed quantitatively as the milk-to-plasma (M/P) ratio. This ratio should not be used as the sole determinant of whether a drug is safe for use during breast-feeding (see Estimating Infant Exposure section).

Several parameters affect drug excretion into breast milk (Table 49-6). The pK_α of a drug partially determines how much drug can reach the milk, because only the nonionized portion of free drug is transferred. Human milk, with an average pH of 7.1, is slightly more acidic than plasma. In general, drugs that are weak acids (e.g., penicillin) tend to have a higher concentration in plasma than milk (M/P <1). Conversely, the concentration of weak bases (e.g., erythromycin) in milk are more likely to be higher or to reach an equilibrium with that measured in plasma (M/P ≥1).[38,219,233] Once in the milk, the proportion of ionized weak base rises in the relatively acidic solution, and thus drug trapping occurs. Drug reabsorption has been found for some agents, and the prevention of passage back into the plasma by trapping may be clinically important. Lipid solubility also is determined to a large extent by the degree of ionization because drugs with relatively high lipid solubility exist in the nonionized form. Diffusion through lipid membranes is probably the most important pathway for drug transfer. Although pH, pK_α, and lipid solubility are important elements, other factors may significantly modify predictions based solely on these chemical characteristics. Two of these other factors are protein binding and molecular weight.[38,233] Drugs with high molecular weights such as insulin (MW >6,000) are less likely to transfer into breast milk, whereas those less than 300 transfer more readily.[38] Highly protein-bound drugs such as glyburide (99% protein bound) are less likely to be transferred into breast milk, although infants should still be monitored for signs of hypoglycemia.

Table 49-6

Factors Affecting the Fate of Drugs in Milk and the Nursing Infant

Maternal Parameters
Drug dosage and duration of therapy
Route and frequency of administration
Metabolism
Renal clearance
Blood flow to the breasts
Milk pH
Milk composition
Drug Parameters
Oral bioavailability (to mother and infant)
Molecular weight
pK_a
Lipid solubility
Protein binding
Infant Parameters
Age of the infant
Feeding pattern
Amount of breast milk consumed
Drug absorption, distribution, metabolism, elimination

pK_a, dissociation constant.

Studying drugs in human milk: time to unify the approach. J Hum Lact. 2002;18:323; Bennett PN, ed. Drugs and Human Lactation. 2nd ed. New York, NY: Elsevier; 1996; Hale TW. Medications and Mothers' Milk. 16th ed. Amarillo, TX: Pharmasoft Medical Publishing; 2014.

Drug transfer also is influenced by the yield of milk, which is related to blood flow and PRL secretion.[233] Lactation is associated with a high blood flow to the breasts, but little is known about this flow during or between feedings. The milk yield (volume) differs slightly depending on the duration of lactation and the time of day. A diurnal pattern has been observed, with highest yields at 6 AM and lowest yields at 6 PM or 10 PM. The mean composition of mature human milk is approximately 87% aqueous solution, 3.5% lipids, 8% carbohydrate (83% of which is lactose), 0.9% protein, and 0.2% nitrogen.[233] The proportions of these components may vary widely from woman to woman and even within the same woman. For example, hind milk (breast milk that is expressed last and contains more fat) contains fourfold to fivefold the fat content of foremilk (breast milk that is expressed first and is high in water content, water-soluble vitamins, carbohydrates, and protein), whereas colostrum (first milk, secreted late in pregnancy and in the first few days after delivery) contains little fat. Fat content also has exhibited a diurnal variation.

After a drug reaches the milk, it equilibrates between the aqueous and lipid phases. The nature of this equilibration can modify how much drug actually reaches the infant. Infant feeding patterns differ significantly from one baby to another. The time spent suckling at each breast, and the volume of milk taken in, also determine the amount of drug ingested, especially if the drug has partitioned into one phase more so than the other. Once the infant ingests the drug via breast milk, the pharmacologic and adverse effects on the infant will be determined by the extent of oral bioavailability, distribution, metabolism, and rate of elimination. These pharmacokinetic parameters differ, depending on the infant's age and whether he or she was born prematurely or at term.

CASE 49-12

QUESTION 1: H.P. is a 25-year-old woman G3, P3 who recently was diagnosed with a distal deep vein thrombosis (DVT) in her lower left extremity confirmed by a Doppler ultrasound at 5 weeks' gestation. She has a significant history of having multiple DVTs in her prior pregnancies, and her thrombophilia workup was negative. During her pregnancy, she was on therapeutic low-molecular-weight heparin (LMWH) 80 mg (weight, 76 kg) SC every 12 hours. Her dosage was increased to 100 mg SC every 12 hours after subsequent anti-factor Xa levels were subtherapeutic. Her LMWH was discontinued 24 hours before she received an epidural for labor pain. After delivery, H.P. is restarted on LMWH and then changed to warfarin on day 5. H.P. also is breast-feeding. Do either of these drugs present a risk to the nursing infant?

Heparin does not cross into breast milk (see Drug Excretion in Human Milk section) because of its high molecular weight (~12,000) and is therefore safe in breast-feeding. Warfarin is a weakly acidic drug (pK_α 5.05) that is highly ionized at physiologic

---

pH (>99%) in maternal serum.[233] It also is highly protein bound (97%).[38] These pharmacokinetic parameters make warfarin very unlikely to transfer into breast milk. Case reports in lactating mothers confirm that warfarin is not detected in breast milk or infant plasma.[38] The American Academy of Pediatrics (AAP) considers warfarin compatible with breast-feeding,[92] and it is widely considered to be safe in breast-feeding.[92,235] There are no studies to guide duration of anticoagulation in women who have had a DVT associated with pregnancy. However, most recommend anticoagulation for at least 6 weeks postpartum, with total duration of anticoagulation of a minimum of 6 months after the thromboembolic event.[235] H.P. can safely breast-feed her infant while she is on LMWH and warfarin.

Estimating Infant Exposure

The actual amount an infant will ingest is difficult to determine owing to varying maternal, drug, and infant parameters. Available data generally are from single or small numbers of case reports or pharmacokinetic studies involving few mother–infant pairs. An M/P ratio is sometimes used alone as the basis for a recommendation, but this should be avoided because its accuracy can be affected by many factors such as the time of sampling after maternal ingestion (peak versus steady state), dose, length of therapy, route of administration, and milk composition.[233] A RID is sometimes reported in resources or literature, which is expressed as a percentage of the maternal dose.[233] Generally, an RID of less than 10% is interpreted as an acceptable level. This must be interpreted with caution, however, taking into account other variables such as the age and health of the infant and the safety profile of the drug. It is also important to note that these are estimated values, often based on data collected from one or only a few individuals. Applying these equations using measurements specific to a woman and her infant is not clinically practical, however. Compared with the M/P ratio, experts believe that the RID is a better estimate of infant exposure.

Sampling during maternal peak drug concentration attempts to approximate the highest amount of drug that can reach the infant. This assumption is inherently flawed because peak drug concentration in the mother does not necessarily equate with peak drug concentration in milk at that same point in time.[233,236] The amount of drug an infant actually receives also depends on the volume of milk ingested. Even if a drug has a high M/P ratio, the actual amount received by the infant could be low if only a small volume of milk was consumed. Therefore, an M/P ratio describes the likelihood of drug excretion into breast milk, but it does not indicate the level of infant exposure. In general, drugs with lower M/P ratios (<1) are preferred over those with higher M/P ratios (>1) during breast-feeding, but other parameters such as maternal condition and therapeutic efficacy should be considered.

Infant exposure to a drug via ingestion of breast milk can be estimated for some drugs. The M/P ratio is used to estimate the drug concentration in milk (Eq. 49-1) and the dose the infant may ingest (Eq. 49-2).[233,236,237] The variables required to calculate Equation 49-1 can be located in the published literature, but only for some drugs. The actual volume of milk ingested by the infant is difficult to estimate, but the average consumption is approximately 150 mL/kg/day. The estimated infant dose can then be used to calculate an RID, which is expressed as a percentage of the maternal dose.[236]

$$\text{Drug concentration in milk} = \text{Maternal plasma drug concentration} \times M/P \qquad \text{(Eq. 49-1)}$$

$$\text{Infant dose (mg/kg/day)} = \text{Drug concentration in milk} \times \text{milk volume (mL/kg/day)} \qquad \text{(Eq. 49-2)}$$

$$\text{RID \%} = \text{Infant dose (mg/kg/day)/maternal dose (mg/kg/day)} \times 100 \qquad \text{(Eq. 49-3)}$$

CASE 49-13

QUESTION 1: K.J., a breast-feeding, 91-kg woman, is taking hydrochlorothiazide 50 mg PO daily. The drug has a long elimination half-life of about 12 hours. Peak milk levels of the drug occur 5 to 10 hours after a dose. In a recent study, the drug was excreted into milk with a mean concentration of 80 ng/mL. Based only on dose, does this drug represent a significant risk to K.J.'s nursing infant?

The maternal dose is 50 mg/91 kg = 0.55 mg/kg/day. The infant dose is calculated to be 80 ng/mL (1 mcg/1,000 ng) (1 mg/1,000 mcg) (150 mL/kg/day), which equals 0.012 mg/kg/day. The RID equals the actual infant dose (0.012 mg/kg/day) divided by the actual maternal dose (0.55 mg/kg/day) × 100, which equals 2.18%. Therefore, the exposure likely does not represent a risk. K.J. can continue to take hydrochlorothiazide while breast-feeding. The AAP classifies hydrochlorothiazide as compatible with breast-feeding.[38,92]

Reducing Risk of Exposure

If pharmacologic treatment is medically necessary for a nursing mother, every attempt should be made to minimize infant exposure to the drug. Methods of reducing risks have been proposed.[229,233,234] Table 49-7 summarizes critical factors that should be considered. Except for drugs that are contraindicated during lactation, the decision to continue or discontinue nursing while receiving medication is ultimately the mother's. Therefore, patient education is an integral component in this decision-making process. The mother should be informed of the potential risks, or lack thereof, associated with a drug. She also should be made aware that certain risks may be minimized by altering feeding pattern and drug administration time and by carefully monitoring the infant for early signs of adverse effects.

Table 49-7

Reducing Risk of Infant Exposure to Drugs in Breast Milk

A drug should be used only if medically necessary, and treatment cannot be delayed until the infant is ready to be weaned

Drug Selection
Consider whether the drug can be safely given directly to the infant
Select a drug that passes poorly into breast milk with the lowest predicted M/P ratio, and an RID <10%
Avoid long-acting formulations (e.g., sustained release)
Consider possible routes of administration that can reduce drug excretion into milk
Determine length of therapy and if possible avoid long-term use
Feeding Pattern
Avoid nursing during times of peak drug concentration
If possible, plan breast-feeding before administration of the next dose
Other Considerations
Always observe the infant for unusual signs (e.g., sedation, irritability, rash, decreased appetite, failure to thrive)
Discontinue breast-feeding during the course of therapy if the risks to the fetus outweigh the benefits of nursing
Provide adequate patient education to increase understanding of risk factors

M/P, milk-to-plasma ratio; RID, relative infant dose.

Source: Anderson PO. Drugs and breast milk [letter]. Pediatrics. 1995;95:957; Begg EJ et al. Studying drugs in human milk: time to unify the approach. J Hum Lact. 2002;18:323; Howard CR, Lawrence RA. Drugs and breastfeeding. Clin Perinatol. 1999;26:447.

Table 49-8

Drugs Considered Contraindicated During Lactation

Drug or Drug Class	Effects on Nursing Infants
Amphetamines[a]	Accumulate in breast milk and may cause irritability and poor sleep patterns
Antineoplastics	Potential for immune suppression; cytotoxic effects of drugs on dividing cells in infants unknown[2]
Cocaine[a]	Excreted in milk; contraindicated because of CNS stimulation and intoxication
Ergotamine	Potential for suppressing lactation; vomiting, diarrhea, and convulsions have been reported.[92] Considered contraindicated by some clinicians. AAP recommends using with caution
Heroin[a]	Possible addiction if sufficient amounts ingested
Immunosuppressants	Potential for immune suppression
Lithium	Milk and serum concentrations average 40% of maternal serum levels. Potential for toxicity exists. Considered contraindicated by some clinicians. AAP recommends using with caution
Lysergic acid diethylamide (LSD)[a]	Probably excreted in milk
Marijuana[a]	Excreted in milk
Misoprostol	Excretion in milk has not been studied but contraindicated because of potential for severe diarrhea in infant

Phencyclidine[a]	Potent hallucinogenic properties
Phenidone	Massive scrotal hematoma and wound oozing after herniotomy in one infant; contraindicated
Requiring Temporary Cessation of Breast-Feeding	
Radiopharmaceuticals	Halt breast-feeding temporarily to allow clearance of radioactivity from milk. Suggested times for individual agents are as follows: copper-64 (${}^{64}\text{Cu}$) 50 hours; gallium-67 (${}^{67}\text{Ga}$) 2 weeks; indium-111 (${}^{111}\text{In}$) 20 hours; iodine-123 (${}^{123}\text{I}$) 36 hours; iodine-125 (${}^{125}\text{I}$) 12 days; iodine-131 (${}^{131}\text{I}$) 2–14 days; radioactive sodium 96 hours; technetium-99m (${}^{99\text{m}}\text{Tc}$) 15 hours–3 days; (${}^{99\text{m}}\text{TcO}_4$) (${}^{99\text{m}}\text{Tc}$ macroaggregates) 15 hours–3 days

This list is not all-inclusive. Selected drugs are listed by drug class and not by individual names.

[a] All drugs of abuse are contraindicated during lactation.

Philadelphia: Lippincott Williams & Wilkins; 2017; Sachs HC and the American Academy of Pediatrics Committee on Drugs. Transfer of drugs and therapeutics into human milk. Pediatrics. 2013;132(3);e796–e809; Hale TW. Medications and Mothers' Milk. 16th ed. Amarillo, TX: Pharmasoft Medical Publishing; 2014.

Resources for Drugs and Lactation

Comprehensive sources reviewing drug use in lactation are available to assist clinicians in weighing the potential risks versus benefits of mothers using medications while breast-feeding. Table 49-8 lists some medications that are contraindicated during lactation. The AAP Committee on Drugs periodically reviews the transfer of drugs and other chemicals into human milk and publishes their findings.[92] The Committee identifies drugs that should be avoided during breast-feeding, drugs that should be used with caution, drugs whose effects on infants are unknown but of concern, and those considered usually compatible with breast-feeding. This rigorous review is an ongoing process, and new guidelines are published every few years; therefore, the reader should locate the latest AAP recommendations available. In addition to the AAP guidelines, several other references also offer comprehensive information and recommendations on drug use in lactation.[38,92,234]

Most drugs are excreted into breast milk to some extent; the reader is referred to specialty sources for an in-depth review of the drug in question. The best sources for information regarding drugs in lactation are (a) Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk by Briggs, Freeman, and Yaffe[38] and (b) TOXNET, an online lactation database (LactMed) sponsored by the NIH, accessible at **http://toxnet.nlm.nih.gov** and click on LactMed. These two databases are peer-reviewed and contain referenced sources. Categories assigned to these drugs may change because new data become available for specific drugs.

ACKNOWLEDGMENT

The author acknowledges Kimey D. Ung, Jennifer McNulty, and Gerald G. Briggs, BPharm, for their contributions to this chapter in earlier editions.

Disorders Related to the Menstrual Cycle

Laura M. Borgelt and Karen M. Gunning

CORE PRINCIPLES

		CHAPTER CASES
1	A normal menstrual cycle involves the hypothalamus, anterior pituitary gland, ovaries, and endometrial lining of the uterus to create hormonal release. This process results in follicle development, ovulation, and either pregnancy or menstruation every 28 days (average) during reproductive life.	
2	Polycystic ovary syndrome (PCOS) is a heterogeneous disorder that presents with signs and symptoms of hyperandrogenism (e.g., acne, hirsutism) or ovulatory dysfunction.	**Case 50-1 (Question 1), Figure 50-3**
3	Long-term complications of PCOS may include impaired glucose tolerance, diabetes, metabolic syndrome, infertility, endometrial cancer, and obstructive sleep apnea.	**Case 50-1 (Question 2)**
4	Treatment for PCOS involves nonpharmacologic and pharmacologic management. Pharmacologic management targets the pathophysiologic aspects of the syndrome and individual goals of treatment. Oral contraceptives are preferred when contraception is desired; letrozole or clomiphene citrate is warranted when pregnancy is desired.	**Case 50-1 (Questions 3–7), Table 50-1**
5	Dysmenorrhea, or painful cramping that occurs with the onset and first days of menstruation, can be categorized as either primary (without underlying uterine pathology) or secondary as a result of uterine conditions, including endometriosis, uterine polyps, or fibroids; complications of intrauterine contraceptive device use; or pelvic inflammatory disease. A careful history can distinguish most cases of primary dysmenorrhea that can be effectively treated with over-the-counter medications from secondary dysmenorrhea, which should always be investigated further for its underlying etiology.	**Case 50-2 (Questions 1, 2), Table 50-2**
6	Dysmenorrhea is the single largest cause of lost productivity and school absence among adolescent girls. Healthcare providers can play a significant role in patient education and development of rational evidence-based drug therapy plans that include nonsteroidal anti-inflammatory drugs (NSAIDs) or hormonal contraceptives to decrease symptoms and improve functionality.	**Case 50-2 (Questions 3–8)**
7	Endometriosis is defined as the presence of functional endometrial tissue occurring outside the uterine cavity. It is the most common cause of	**Case 50-3 (Question 1), Table 50-3**

	secondary dysmenorrhea in young women and can result in chronic pelvic pain, infertility, and dyspareunia. A significant delay in diagnosis of endometriosis is common and can result in negative effects on fertility and pain control. Recognition of the potential for a diagnosis of endometriosis, through a careful history and physical examination, is a key for clinicians to provide appropriate care.	
8	Pain control in endometriosis is directed at suppression of endometrial implants that respond to estrogen with bleeding, resulting in subsequent inflammation and pain. Pharmacologic therapy is directed at reducing inflammation (via use of NSAIDs) and reduction in estrogen (through use of hormonal contraception), or the use of gonadotropin-releasing hormone (GnRH) analogs to induce a pseudomenopausal state. A treatment plan should take into account cost, ease of use of therapy, and the patient's desire for future fertility.	**Case 50-3 (Questions 2–4), Case 50-4 (Question 1), Case 50-5 (Question 1), Table 50-4**

9	Endometriosis treatment plans that include GnRH analogs or aromatase inhibitors may also require the use of "add-back" therapy. Add-back therapy is the addition of progestins or estrogens that may be used with GnRH analogs and aromatase inhibitors to decrease menopausal side effects including hot flashes, vaginal dryness, and decreases in bone density.	**Case 50-4 (Question 1), Table 50-4**
10	More than 200 premenstrual symptoms (such as increased energy, libido, ability to relax, abdominal distension, fatigue, headaches, and crying spells) have been described as occurring during the days before menstruation. It is not until the symptoms have a decidedly negative influence on the physical, psychological, or social function of a woman that premenstrual syndrome (PMS) or premenstrual dysphoric disorder (PMDD) exists. Both PMS and PMDD have symptoms that occur in the luteal phase with resolution within a few days of menstruation, lasting across at least two menstrual cycles, and disrupt normal activities.	**Case 50-6 (Questions 1, 3), Tables 50-5 and 50-6**
11	Nonprescription options that have been studied and have shown at least minimal benefit in PMS and PMDD include calcium, magnesium, pyridoxine, chaste tree or chasteberry, and some mind–body approaches.	**Case 50-6 (Question 2)**
12	Treatment for PMS and PMDD includes lifestyle modifications, psychological interventions, selective serotonin reuptake inhibitors (SSRIs), other psychotropic medications, oral contraceptives, GnRH agonists, and danazol. Because serotonin is critical in the pathogenesis of these disorders, SSRIs have become the treatment of choice for PMDD and severe PMS.	**Case 50-6 (Question 4), Table 50-7**

MENSTRUAL CYCLE PHYSIOLOGY

Feedback biologic mechanisms involving the hypothalamus, anterior pituitary gland, ovaries, and endometrial lining of the uterus control the average 28-day menstrual cycle.[1–3] The hypothalamus synthesizes gonadotropin-releasing hormone (GnRH) and secretes the hormone in a pulse-like manner with varying frequencies throughout the menstrual cycle (typically every 60–90 minutes). GnRH stimulates the anterior pituitary to produce and release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH is important for stimulating growth of ovarian follicles, and LH is critical for ovulation and sex steroid production. FSH and LH act on the ovaries to produce estrogen and progesterone. Estrogen in turn acts on the hypothalamus and anterior pituitary, in a negative feedback manner, to stop FSH and LH secretion (Fig. 50-1).

The menstrual cycle can be divided into three phases: the follicular phase, ovulation, and the luteal phase (Fig. 50-2).[1–3] The day bleeding begins is referred to as the first day (or day 1) of the menstrual cycle. Bleeding usually occurs from days 1 to 5 of the cycle, although may be longer in some women. The follicular phase begins at the onset of menstruation and lasts approximately 10 to 14 days (see Fig. 50-2). At the beginning of this phase, several follicles begin to develop within the ovary. In the second half of the follicular phase most of the developing follicles atrophy, while the dominant follicle develops further and produces estrogen in increasing amounts. Elevated estradiol levels during the ovulatory phase lead to a surge in LH and FSH. The LH surge is responsible for final-stage growth and maturation of the follicle, ovulation, and the formation of the corpus luteum. Ovulation usually occurs 14 days before the last day of the cycle and is followed by the luteal phase. The luteal phase is 13 to 15 days in duration and is the least variable part of the human reproductive cycle.[1] During this progesterone-dominant phase, the corpus luteum produces progesterone and estrogen. Progesterone prepares the endometrium for implantation of a fertilized ovum. If implantation does not occur, corpus luteum regression causes a decrease in the levels of estrogen and progesterone. When these hormone levels decrease, the endometrium cannot be maintained and is sloughed off (menstrual phase). Using the average 28-day cycle as an example, day 28 is the last day of the cycle and is the day before bleeding begins again for the next menstrual cycle.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) affects approximately 6% to 15%, or approximately 1 in 10, women of reproductive age, making it the leading cause of anovulatory infertility and the most common endocrine abnormality for this age group.[4] This syndrome, or constellation of symptoms, was first described in 1935 by Stein and Leventhal when they reported infertility and amenorrhea in seven women with enlarged cystic ovaries.[5] Excessive male-patterned hair growth and obesity were added later to the description of this syndrome.[6] PCOS also has been referred to as Stein-Leventhal syndrome, polycystic ovary, polycystic ovarian disease, hyperandrogenic chronic anovulatory syndrome, and functional ovarian hyperandrogenism. The name polycystic ovary syndrome has been most widely accepted because "syndrome" best describes the heterogeneous nature of this disorder. However, there have been recommendations to change the name because it focuses on the polycystic ovarian morphology, which is not necessary for diagnosis.[7] It has been suggested that the name should include the complex metabolic, hypothalamic, pituitary, ovarian, and adrenal interactions of the syndrome.

Diagnostic Criteria

The diagnosis of PCOS is complicated by variations among women presenting signs and symptoms of PCOS and because precise and uniform criteria for diagnosis have not been firmly established. Three major diagnostic criteria for PCOS have been proposed by different organizations.

The initial diagnostic criteria were developed in 1990 during an expert conference sponsored by the US National Institutes of Health and US National Institute of Child Health and Human Development. The panel concluded that the major criteria for PCOS should include (in order of importance) the following: (a) hyperandrogenism (clinical signs of hyperandrogenism such as hirsutism) or hyperandrogenemia (biochemical signs of hyperandrogenism such as elevated testosterone levels), (b) oligo-ovulation (infrequent or irregular ovulation with fewer than nine menses/year), and (c) exclusion of other known disorders such as hyperprolactinemia, thyroid abnormalities, and congenital adrenal hyperplasia.[8] The second set of criteria was proposed at an expert conference in Rotterdam sponsored by the European Society for Human Reproduction and Embryology and the American Society for Reproductive Medicine in 2003.[9] They concluded that the presence of two of these three features, after exclusion of related disorders, confirmed diagnosis of PCOS: (a) oligo-ovulation or anovulation, (b) clinical or biochemical signs of hyperandrogenism, or (c) polycystic ovaries. The third set of criteria was developed by a task force of the Androgen Excess Society in 2006 with a complete report including phenotyping in 2009.[10,11] Their criteria include hyperandrogenism (hirsutism or hyperandrogenemia), ovarian dysfunction (oligo-ovulation or polycystic ovaries), and exclusion of other androgen excess or related disorders. Recent practice guidelines support the Rotterdam criteria for diagnosing PCOS.[12]

Criteria for diagnosis of PCOS in adolescence can be difficult to assess due to typical changes during puberty and are different from those used for older women of reproductive age.[4] Specifically, all three Rotterdam criteria should be present or oligomenorrhea or amenorrhea should be present for at least 2 years after menarche (or primary amenorrhea at age 16 years), the diagnosis of polycystic ovaries on ultrasound should include increased ovarian size (>10 cm^3), and hyperandrogenemia rather than just signs of androgen excess should be documented.

Clinical Characteristics

Common clinical signs of hyperandrogenism in PCOS include hirsutism, acne, and alopecia. Hirsutism, the most common of these characteristics, occurs in 60% to 75% of women with PCOS.[4,10–11]

It is defined as an excess of thickly pigmented body hair in a male pattern distribution and commonly found on the upper lip, lower abdomen, and around the nipples. Women seeking treatment for hirsutism may be evaluated for PCOS. Acne affects 15% to 25% of women with PCOS, but this prevalence may not be different from the general population. The prevalence of alopecia occurrence varies widely with reports of 5% to 50% of women with PCOS and presents as scalp hair loss in the crown and vertex areas.[10,13] Although hirsutism is considered a good marker of hyperandrogenism, acne and alopecia should not be regarded as evidence of hyperandrogenism.

Ovulatory dysfunction in PCOS is typically described as oligo-ovulation or anovulation, presenting clinically as a woman with irregular menstrual cycles. Overall, 95% of women with PCOS and oligo-ovulation have menstrual dysfunction, usually oligomenorrhea or amenorrhea.[4] The menstrual disturbances usually begin in the peripubertal years; however, menstrual cycles in women with PCOS become more regular because they approach menopause.[14] Obesity (defined as a body mass index [BMI] ≥ 30 kg/m^2) occurs in approximately 61% to 76% of women with PCOS.[4] Central or abdominal obesity is the typical pattern. Central obesity is a risk factor for the development of diabetes and heart disease and, when present in a woman with PCOS, worsens the clinical features (e.g., insulin resistance) of the syndrome.[4,15] Therefore, lifestyle modification with appropriate diet and exercise is a cornerstone of therapy for many women with PCOS.

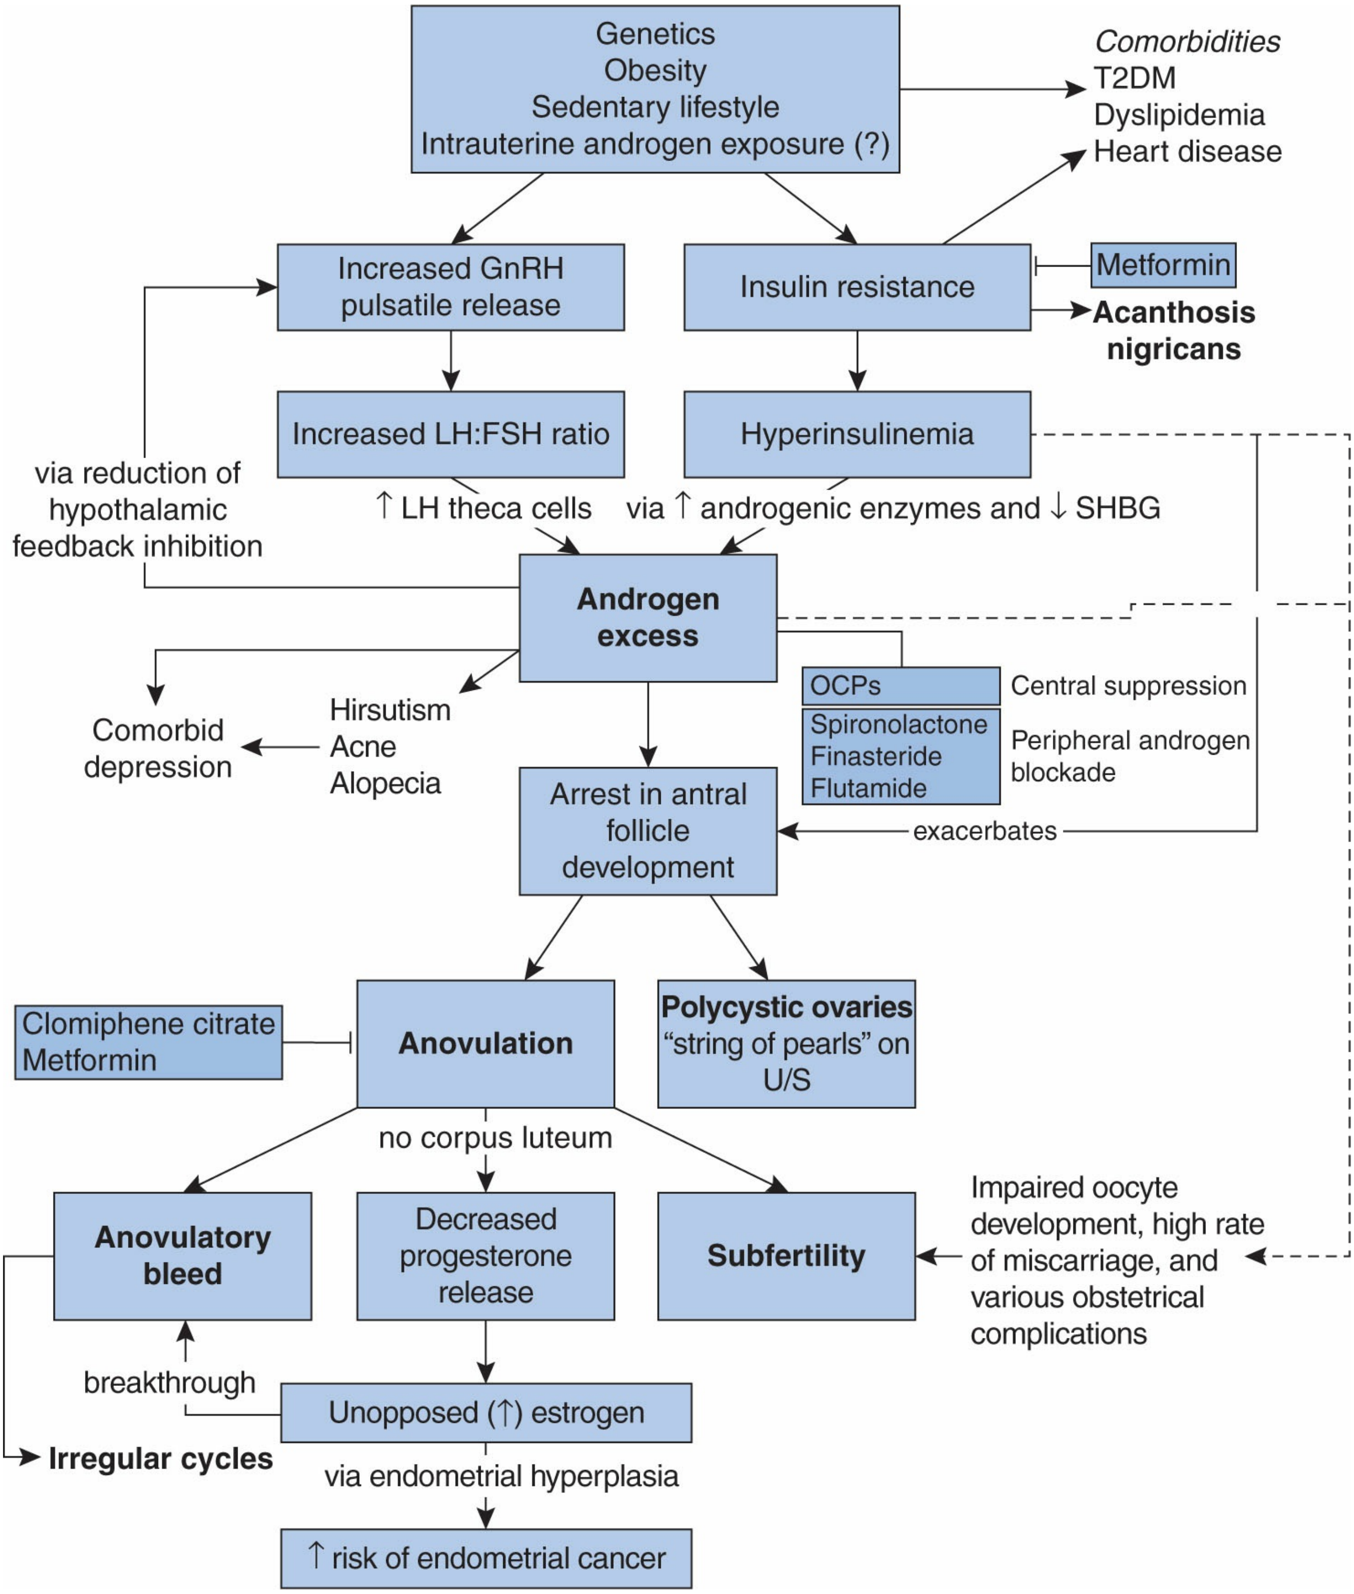
Pathophysiology

The pathophysiology of PCOS is complex. The primary defect in PCOS is unknown, but at least three potential mechanisms, acting alone or synergistically, appear to create the characteristic clinical presentation. These mechanisms include inappropriate gonadotropin secretion, excessive androgen production, and insulin resistance with hyperinsulinemia. Figure 50-3 displays the closely integrated relationship between these mechanisms in the development of PCOS.

A genetic basis for PCOS has been postulated, but its mode of transmission is unclear.[7,16] Theories include an autosomal-dominant model and a polygenic model with genetic–environmental interactions. The complex presentation and various mechanisms make it impossible to target just one gene locus; in fact, more than 50 candidate genes have been proposed. A familial pattern to the development of PCOS may exist, because the incidence is higher in women with relatives with the disorder.

GONADOTROPIN SECRETION

In PCOS, there is an increased frequency of GnRH stimulation, leading to an increase in LH pulse frequency and amplitude, whereas FSH secretion remains normal. The development of a dominant follicle does not occur because LH secretion occurs too early in the menstrual cycle. Therefore, a woman is left with several immature follicles and usually will not ovulate. It is not clear whether the abnormal pulse frequency of GnRH is an intrinsic problem in the GnRH pulse generator in the hypothalamus or a result of relatively low progesterone concentrations from infrequent ovulation.[17] A woman with this abnormality does not enter the luteal phase of her menstrual cycle, leaving estrogen unopposed. Unopposed estrogen leads to endometrial hyperplasia and increases the risk for endometrial cancer. Increased LH stimulation also leads to increased steroidogenesis in the ovary, leading to excess androgen production. Amenorrheic women have high antimullerian hormone (AMH) serum concentrations and higher antral follicle counts compared with both oligomenorrheic women and regularly cycling patients with PCOS.[4] Additionally, concentrations of AMH tend to remain persistently elevated over time in women with PCOS.



Genetics
Obesity
Sedentary lifestyle
Intrauterine androgen exposure (?)
Comorbidities
T2DM
Dyslipidemia
Heart disease
Increased GnRH pulsatile release
Insulin resistance
Metformin
Acanthosis nigricans
Increased LH:FSH ratio
Hyperinsulinemia
via reduction of hypothalamic feedback inhibition
↑ LH theca cells
via ↑ androgenic enzymes and ↓ SHBG
Androgen excess
OCPs
Central suppression
Spironolactone
Finasteride
Flutamide
Peripheral androgen blockade
Comorbid depression
Hirsutism
Acne
Alopecia
Arrest in antral follicle development
exacerbates
Clomiphene citrate
Metformin
Anovulation
Polycystic ovaries
"string of pearls" on U/S
no corpus luteum
Anovulatory bleed
Decreased progesterone release
Subfertility
Impaired oocyte development, high rate of miscarriage, and various obstetrical complications
breakthrough
Unopposed (↑) estrogen
Irregular cycles
via endometrial hyperplasia
↑ risk of endometrial cancer

EXCESS ANDROGEN PRODUCTION

Androgen production occurs in the theca cell of the ovary to facilitate follicular growth and estradiol synthesis in the granulosa cell. In women with PCOS, hypersecretion of LH and insulin increases the production of androgens, causing abnormal sex steroid synthesis, hyperandrogenism, and hyperandrogenemia. The dysregulation in steroid synthesis and metabolism is believed to result primarily from a dysfunction of the cytochrome P-450 (CYP) C17 enzyme in the ovaries, an enzyme with 17-hydroxylase and 17,20-lyase activities that are required to form androstenedione.[17,18] Androstenedione is then converted to testosterone or is aromatized by the aromatase enzyme to form estrone. Theca cells in women with PCOS are more efficient at the conversion to testosterone than normal theca cells.[19] Also, a similar steroid pathway occurs in the adrenal cortex and, when hyperandrogenism or hyperinsulinemic states exist, androgen production is further enhanced.

Elevated androgen levels are seen in approximately 60% to 80% of women with PCOS, mostly as increased free testosterone concentrations.[10,11] Assays for testosterone tend, however, to be highly variable and inaccurate, so measurement of androgen concentrations should be used only as an adjuvant test and never as the sole criterion for diagnosis. Clinical assessment is the primary tool for assessment of excess androgen.

INSULIN

Women with PCOS generally exhibit an increased risk of insulin resistance, yet the cellular and molecular mechanisms for insulin resistance are different from those seen with obesity and type 2 diabetes.[4] Insulin resistance is associated with reproductive and metabolic abnormalities in women with PCOS and can occur in both obese and nonobese women. There are several mechanisms by which this occurs. One proposed mechanism is a postbinding defect in insulin-receptor signaling.[20] Specifically, abnormal receptor autophosphorylation increases serine phosphorylation in targeted cells, which contributes to insulin resistance.[21,22] The insulin resistance in PCOS has been shown to be a selective, tissue-specific process where insulin sensitivity is increased in the ovarian androgenic pathway (causing hyperandrogenism), but insulin resistance is seen in other tissues involved with carbohydrate metabolism, specifically in the fat and muscle. Hyperinsulinemia results because of the compensatory increase in insulin secretion secondary to insulin resistance.

Insulin has both direct and indirect roles in PCOS. In the ovary, insulin acts alone or synergistically with LH to increase androgen production in theca cells. In the liver, insulin inhibits synthesis of sex hormone–binding globulin (SHBG), a key protein that binds to testosterone, and thus increases the free fraction of androgens available for biologic activity. Therefore, hyperinsulinemia is a major contributor to both hyperandrogenism and hyperandrogenemia in PCOS. Treatments targeted to improve insulin resistance in women with PCOS have shown improvements in ovulatory function, hirsutism, androgen levels, and metabolic profiles.[23,24] Indirectly, insulin may enhance the amplitude of LH pulses, further exacerbating the gonadotropin secretion defect in PCOS.[25]

CASE 50-1

QUESTION 1: E.F. is a 27-year-old woman with mild hair growth above her upper lip, mild acne, and a history of irregular menstrual periods. Since age 12, she has had six to nine periods/year at intervals that vary from 30 to 90 days. When she does have a period, she considers them to be "normal" without pain or excessive bleeding. Her irregular periods were not bothersome until recently when she became sexually active and worries about becoming pregnant. She uses condoms for birth control. She reports no other medical conditions.

E.F. is 5 feet 7 inches tall and weighs 180 lb (BMI 28.2 kg/m^2). Her vital signs today are blood pressure (BP) 118/84 mm Hg, heart rate (HR) 70 beats/minute, temperature 98.6°F, and respiratory rate (RR) 18 breaths/minute. Her physical examination is normal, with the exception of noted excessive facial hair and mild acne. She takes a multivitamin daily and acetaminophen as needed for headaches. She has no known medication allergies. What signs and symptoms does E.F. have that are consistent with PCOS?

E.F. exhibits several signs and symptoms that would indicate the presence of PCOS. According to the criteria of all organizations, her history of abnormal menstrual periods (oligomenorrhea) and clinical signs of hyperandrogenism, including hirsutism and acne, would indicate PCOS. Furthermore, her combination of hyperandrogenemia and oligomenorrhea signifies the highest metabolic risk among PCOS patients.[4] E.F. is overweight, which is common in women with PCOS but is not considered a criterion for diagnosis. Before a diagnosis of PCOS is made, laboratory testing to exclude other related causes of her symptoms would have to be performed. Studies may include prolactin, thyroid-stimulating hormone, testosterone, and 17-hydroxyprogester-one concentrations to rule out hyperprolactinemia, hypothyroidism, virilizing tumor, and congenital adrenal hyperplasia, respectively. PCOS is primarily diagnosed by clinical assessment; therefore, these tests assist only in confirming or excluding a diagnosis. To determine the presence of polycystic ovaries, defined as more than eight follicles per ovary that are less than 10 mm (usually 2–8 mm) in diameter, a transvaginal ultrasound should be performed.

Long-Term Complications

CASE 50-1, QUESTION 2: E.F has a mother with diabetes and hypertension and a father with diabetes, hypertension, and dyslipidemia. Her significant laboratory values include the following:

Fasting glucose, 102 mg/dL
Low-density lipoprotein (LDL), 150 mg/dL
High-density lipoprotein (HDL), 52 mg/dL
Triglycerides, 130 mg/dL
Total cholesterol, 228 mg/dL
What risk does E.F. have for experiencing long-term complications from PCOS?

E.F. has an increased risk for experiencing impaired glucose tolerance, diabetes, and metabolic syndrome, especially considering her family history. Furthermore, the diagnosis of PCOS places her at possible increased risk for sleep apnea and endometrial cancer.

IMPAIRED GLUCOSE TOLERANCE AND DIABETES

Studies have shown that women with PCOS have a higher prevalence of impaired glucose tolerance, gestational diabetes,

---

diabetes, and insulin resistance compared with women without the syndrome.[4,26,27] A family history increases the risk of these conditions further. In a study of 254 women with PCOS, 38.6% were found to have either impaired glucose tolerance (IGT) or undiagnosed diabetes.[28] Compared with those without PCOS, the prevalence of IGT and diabetes was significantly higher in both obese and nonobese (BMI <27 kg/m^2) women. Waist–hip ratio and BMI appeared to be the most clinically important predictors of glucose intolerance. Women with PCOS who have IGT appear to exhibit type 2 diabetes at higher rates than the general population.[26,27] Therefore, screening and diagnosis of these conditions is important for women with PCOS. E.F. is overweight, and her mildly elevated fasting glucose and overweight suggest that she may be at increased risk for impaired glucose tolerance.

Glucose tolerance should be assessed in all women with PCOS using a fasting and 2-hour oral (75 g) glucose tolerance test.[4,26,29] Routine screening for diabetes with an oral glucose tolerance test should be performed for all women with PCOS by the age of 30 years.[30] The American Diabetes Association or World Health Organization criteria should be used for the appropriate diagnosis of IGT or diabetes. Insulin concentrations are typically not obtained in clinical settings because they are inaccurate.

METABOLIC SYNDROME AND CARDIOVASCULAR RISK

Approximately one-third to one-half of women with PCOS have metabolic syndrome. Using the National Cholesterol Education Panel-Adult Treatment Panel III criteria,[31–34] metabolic syndrome is present when the patient exhibits any three of these symptoms: abdominal obesity (>40 inches in men and >35 inches in women), triglycerides greater than or equal to 150 mg/dL, low HDL cholesterol (<40 mg/dL in men and <50 mg/dL in women), blood pressure greater than or equal to 130/85 mm Hg, and fasting glucose greater than or equal to 110 mg/dL. The incidence of a metabolic syndrome in women with PCOS is significantly higher than the rate for the general US population (45% vs. 6%, ages 20–29 years; 53% vs. 14%, ages 30–39 years) and independent of body weight.[34] It is believed that insulin resistance and hyperandrogenism are contributing factors to metabolic syndrome in women with PCOS.[35] Insulin resistance in the metabolic syndrome has been associated with a twofold increased risk of cardiovascular disease and a fivefold increased risk of type 2 diabetes.[36] Low HDL cholesterol (HDL-C) is seen most frequently in women with PCOS (68%), followed by increased BMI and waist circumference (67%), high blood pressure (45%), hypertriglyceridemia (35%), and elevated fasting glucose (4%).[32] Another group found that elevated fasting insulin concentrations, obesity, and a family history of diabetes conferred higher risk of having the metabolic syndrome in women with PCOS.[33]

Compared with women without PCOS, women with PCOS are reported to have a higher prevalence of cardiovascular risk factors, including hypertension, dyslipidemia, and surrogate markers for early atherosclerosis (e.g., increased C-reactive protein concentrations).[35] With increasing age, and especially as women with PCOS become postmenopausal, the risk of hypertension increases twofold.[37] Dyslipidemia in women with PCOS typically presents as decreased HDL-C (which is a strong predictor of cardiovascular disease in women), elevated triglycerides, elevated LDL cholesterol (LDL-C), and higher LDL–HDL ratios.[38] Women with PCOS are noted to have more atherogenic, small, dense LDL-C compared with controls, and this substantially increases cardiovascular risk.[39] Altered cholesterol levels are more severe in women with hyperandrogenism.[4] Women with PCOS may have other surrogate markers for early atherosclerosis and cardiovascular disease, impaired endothelial dysfunction, and other markers of cardiovascular risk such as coronary artery calcifications and increased carotid intima-media thickness.[35] Women with PCOS are considered to be at risk when any of these risk factors are present: obesity, cigarette smoking, hypertension, dyslipidemia, subclinical vascular disease, IGT, or family history of premature cardiovascular disease.[40] Non-HDL and waist measurement are the best predictors of CVD risk.[4] They are considered to be high risk when they have metabolic syndrome, type 2 diabetes mellitus, or overt vascular or renal disease. Although cardiovascular risk exists, data are inconclusive about whether women with PCOS have increased rates of morbidity and mortality from cardiovascular disease.

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea is cessation of breathing that occurs during sleep. It can disrupt sleep and cause daytime fatigue. Patients may not be aware that they are having the symptoms of sleep apnea, which include snoring and a gasping or snorting when breathing resumes. Studies indicate that the prevalence of obstructive sleep apnea in the PCOS is higher than expected and cannot be explained by obesity alone.[41–43] Insulin resistance appears to be a strong predictor of sleep apnea—more so than age, BMI, or the circulating testosterone concentration.[43] This can be treated with continuous positive airway pressure (CPAP) and may help metabolic dysfunction.[7]

ENDOMETRIAL HYPERPLASIA AND CANCER

Chronic anovulation in women with PCOS results in an endometrium that is exposed to the prolonged effects of estrogen unopposed by progesterone. Therefore, PCOS is a risk factor for endometrial hyperplasia. Women with PCOS have a 2.7-fold (95%

CI 1.0–7.3) increased risk for endometrial cancer.[4] It is considered prudent management to induce artificial withdrawal bleeding by administering a course of progestin at least every 3 months to prevent endometrial hyperplasia in women with PCOS who experience either amenorrhea or oligomenorrhea. Alternatively, ultrasound scans can also be used to measure endometrial thickness and morphology every 6 to 12 months.

Treatment Goals

CASE 50-1, QUESTION 3: E.F. worries about becoming pregnant when she does not have regular periods. She also has mild hair growth above her upper lip which is somewhat bothersome. Given these concerns, what are the treatment goals for E.F.?

The primary goals for E.F. are to prevent pregnancy and address her hirsutism. Additionally, treatment goals for E.F. would include maintaining a normal endometrium, blocking the actions of androgens at target tissues, reducing insulin resistance and hyperinsulinemia, reducing weight, and preventing long-term complications. Other goals of treatment in patients with PCOS may include correcting anovulation or oligo-ovulation and improve fertility.

Therapy goals should encompass both long-term and short-term objectives because response to nonpharmacologic and pharmacologic therapy is slow, often requiring 3 to 9 months. Addressing long-term goals can minimize the risk for future complications, and specifying short-term goals can improve motivation and adherence to therapy.

NONPHARMACOLOGIC TREATMENT

CASE 50-1, QUESTION 4: E.F. has indicated that she would like to lose weight. E.F. does not smoke, drinks one to two beers on weekends, and exercises by walking 20 minutes twice weekly. What nonpharmacologic method(s) would be most effective?

Weight reduction programs designed for a modest weight loss (5%–10%) with the incorporation of fitness are effective in reducing metabolic disease, cardiovascular risk, and improving ovulatory potential.[40] A 5% to 10% weight loss in E.F. would be 9 to 18 lb. Diet modification and exercise are the most efficient, cost-effective, and safe ways to produce weight loss and improve the endocrine and metabolic parameters of PCOS.[40,44] Weight reduction should be considered first-line therapy in all overweight or obese women with PCOS, and this should be recommended for E.F.

IMPACT OF WEIGHT LOSS IN POLYCYSTIC OVARY SYNDROME

A minimum 5% weight loss has consistently demonstrated restoration of regular menstrual cycling and ovulation in overweight and obese women with PCOS.[15,45,46] When lifestyle modification is implemented, free testosterone concentrations decrease, but clinical outcomes of acne and hirsutism are not often reported.[15] Obesity in PCOS is associated with a higher risk of developing endometrial cancer, but very limited evidence exists to determine the impact of weight loss on the incidence of endometrial cancer.[15] Studies of weight loss in women without PCOS indicate a 25% to 50% reduced risk of endometrial cancer, so it is logical that addressing weight reduction may lower that risk as well.[47,48] The Diabetes Prevention Program trial demonstrated a 53% prevalence of metabolic syndrome; the incidence of this was reduced 41% in the lifestyle modification group.[49,50] This was significantly better than treatment with metformin. Studies specifically evaluating cardiovascular improvements with weight loss in women with PCOS are limited, but improvements in dyslipidemia and insulin sensitivity have been noted.

DIET COMPOSITION

No single diet has been proven to be ideal for women with PCOS. A diet low in saturated fat and high in fiber from mostly low-glycemic-index carbohydrate foods may, however, be suitable and is recommended.[15,51] Glycemic index is a classification of carbohydrates based on the blood glucose response during 2 hours. Low-glycemic index foods include bran cereals, mixed grain breads, broccoli, peppers, lentils, and soy. High-glycemic index foods, or those that should be minimized, include white rice and bread, potatoes, chips, and foods containing simple sugars (e.g., juice). It has been shown that in women with PCOS, oral glucose intake causes larger fluctuations in plasma glucose, increased hyperinsulinemia, and stimulated adrenal steroid secretion; protein was found to be a preferred nutrient over glucose.[52] The composition of a diet should be individualized to promote adherence and achieve specific goals.

EXERCISE

Exercise is a key component in the attainment and maintenance of weight loss. Exercise with muscle strengthening improves insulin sensitivity.[15] The American Heart Association recommends 150 minutes/week of moderate exercise or 75 minutes/week of vigorous exercise.[53] E.F. should continue to eat a healthy diet. A diet consisting of low saturated fats, high fiber, and foods with a low glycemic index should be encouraged. E.F. should increase her exercise to at least 75 minutes/week for at least 3 days of the week. If she is going to continue walking as her exercise, she should walk at a brisk pace. Titrating her time to a goal of exercising 60 minutes daily will help her lose weight.

Pharmacologic Treatment

CASE 50-1, QUESTION 5: E.F. would like to improve her menstrual irregularity, and be sure that she will not get pregnant. If possible, she would also like to minimize her hirsutism and acne. What options would be appropriate to recommend for E.F.?

Several different pharmacologic options could be recommended to E.F (Table 50-1). A combined oral contraceptive (COC) will address her concerns about irregular menstruation, hyperandrogenism, and pregnancy prevention. An insulin sensitizer would improve her menstrual irregularity and possibly reduce her hirsutism and acne, but it does not address her desire to prevent pregnancy. An antiandrogen, such as spironolactone, would address only hyperandrogenism, and other agents would have to be used concurrently to address pregnancy prevention and other hormonal and metabolic alterations in PCOS.

COMBINED ORAL CONTRACEPTIVES

Estrogen–progestin combination therapy with a COC is the treatment of choice for women seeking regularity in menstrual cycles and relief from hyperandrogenic symptoms (see Chapter 47, Contraception, for a list of possible therapies). The estrogen component suppresses LH, resulting in a reduction of androgen production, and increases hepatic production of SHBG, thereby reducing free testosterone. The progestins in various COCs possess variable androgenic effects, so the choice of the COC may be considered to minimize androgenic exposure. The potential effects of COCs on insulin resistance, glucose tolerance, and lipids have been debated, do not appear to increase metabolic risk, and should be considered when choosing a progestin component.[4,54–56] Caution should be used in those who have insulin resistance, a high propensity to develop type 2 diabetes, or abnormal lipid profiles.

Combined oral contraceptive therapy in PCOS should be initiated with a formulation that contains a low dose or very low dose of estrogen (≤35 mcg of ethinyl estradiol) and a progestin with low androgenic or antiandrogen properties. Most COCs manufactured today have low or very low estrogen doses. Desogestrel and norgestimate are progestins with low androgen potential, and drospirenone is an antiandrogen. A COC containing ethinyl estradiol and desogestrel would prevent pregnancy, improve menstrual cycle regularity, and reduce E.F.'s signs of hyperandrogenism (hirsutism and acne). If E.F. desired monthly cycles, she could take the typical 21/7 regimen (21 days active pill, 7 days inactive pill) or a 24/4 regimen (24 days active pill, 4 days inactive pill). Although not specifically evaluated in women with PCOS, a monophasic regimen may also be prescribed using extended cycles of 84 or even 365 days. Extended regimens reduce the number of cycles/year while providing contraception. Regardless of the COC selected, one of the long-term benefits is that her risk for endometrial cancer would be reduced by 50%, even up to two decades after discontinuation.[57–59] Ideal initial contraceptive options for E.F. include 30 to 35 mcg of ethinyl estradiol and a low-androgenic or nonandrogenic progestin such as drospirenone or desogestrel. If she would like to have her menstrual cycle monthly, she should take 21 active pills followed by 7 inactive pills. If she does not desire to have her menstrual cycle, then taking continuous active pills in an extended (daily) manner is most appropriate. This therapy would address her concerns of menstrual irregularity, contraception, hirsutism, and acne. She should continue therapy for as long as she desires contraception and minimization of the androgenic effects of PCOS.

CASE 50-1, QUESTION 6: Two months later, E.F. reports she is experiencing mood swings and weight gain on her ethinyl estradiol/desogestrel oral contraceptive. She is debating whether she wants to continue with the COC and would like to explore other treatment possibilities. What other therapy options may be beneficial for E.F. if she considers this COC to be intolerable?

Table 50-1

Selected Treatment Options for Polycystic Ovary Syndrome (PCOS)

Drug Class (Example)	Purpose of Therapy	Mechanism of Action	Effective Dose	Side Effects
Combined oral contraceptive (estrogen and progestin)	Menstrual cyclicity, hirsutism, acne	Suppresses LH (and FSH) and thus ovarian androgen production; increases sex hormone–binding globulin, which decreases free testosterone	One tablet orally daily for 21 (or 24) days, then 7-day (or 4-day) pill-free interval	Breast tenderness, breakthrough bleeding, mood swings, libido changes
Progestins (medroxyprogesterone)	Menstrual cyclicity	Creates withdrawal bleeding by transforming proliferative endometrium into secretory endometrium	5–10 mg orally daily for 10–14 days every 1–2 months	Breakthrough bleeding, spotting, mood swings
Biguanide (metformin)	Impaired glucose tolerance, type 2 diabetes	Decreases hepatic glucose production, secondarily reducing insulin levels; may have direct effects on steroidogenesis	1,500 mg orally daily in divided doses (up to 2,550 mg/day)	Gastrointestinal problems, diarrhea, abdominal pain
Antiandrogen (spironolactone)	Hirsutism, acne	Inhibits androgens from binding to androgen receptor	50–100 mg orally twice daily	Hyperkalemia, polymenorrhea, headache, fatigue
Antiestrogen (clomiphene citrate)	Ovulation induction	Increases GnRH secretion, which	50 mg orally daily for 5 days; may	Vasomotor symptoms,

		induces rise in FSH and LH	increase to 150 mg	gastrointestinal problems
Aromatase inhibitor (letrozole)	Ovulation induction	Blocks estrogen synthesis to directly affect hypothalamic–pituitary–ovarian function	2.5 mg orally daily for 5 days; may increase to 7.5 mg	

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Metformin

Metformin inhibits hepatic glucose output, providing lower insulin concentrations and reducing androgen production in the ovary. Metformin also appears to influence ovarian steroidogenesis directly.[60,61] Metformin is primarily used for IGT or T2D related to PCOS. Metformin has minimal effectiveness for hirsutism or acne and was found to have no benefit improving rate of miscarriage, fertility, or live-birth rates in anovulatory women with PCOS.[4,62–63] Its routine use for treatment of infertility is not recommended.[4] In a Cochrane systematic review comparing COCs and metformin, metformin demonstrated a reduction in fasting insulin and triglyceride levels compared to oral contraceptives, but greater improvement in menstrual pattern and serum androgen levels was observed with COCs.[56]

The most commonly used and most effective dose of metformin in PCOS is 500 mg orally 3 times daily (TID). It should be titrated slowly to this effective dose; doses up to 2,000 mg daily or 2,550 mg daily may be necessary for individual circumstances. The gastrointestinal (GI) side effects of diarrhea, nausea, vomiting, and abdominal bloating are usually transient and dose-related, and can be minimized by taking with food instead. An estimated glomerular filtration rate (eGFR) should be calculated at least annually in women using metformin because it is contraindicated if eGFR is <30 ml/min/1.73 m^2 and not recommended if eGFR is 30–45 ml/min/1.73 m^2.

AGENTS FOR HIRSUTISM

Although frequently used, antiandrogens do not have FDA-approved uses for the treatment of female hirsutism or acne in the United States. Spironolactone is commonly prescribed to women for hirsutism. Drospirenone (a derivative of spironolactone), found in COCs has antiandrogenic properties and has also been evaluated in the long-term treatment of hirsutism.[64] Finasteride has been used for female hirsutism, but its lack of specificity for type I 5α-reductase in the pilosebaceous unit and toxicity may make this a suboptimal treatment choice. Flutamide is effective for hirsutism, but it is not used because of hepatotoxicity. Eflornithine hydrochloride has been approved for topical use in treating facial hirsutism, but has not been well studied in women with PCOS. Electrolysis and laser treatments may be acceptable physical approaches to hair removal for women with PCOS.

Spironolactone

Spironolactone acts by competitively inhibiting dihydrotestosterone (DHT) from interacting with its androgen receptor. This causes a decrease in activity of ovarian-produced testosterone. Spironolactone reduces hair growth by 40% to 88%; however, it takes 6 to 9 months for improvement.[65] Spironolactone may be associated with possible teratogenicity (feminization of the male fetus), so it is prudent to advise women to avoid pregnancy for at least 4 months after the discontinuation of spironolactone. It is recommended that spironolactone be used with a COC to avoid teratogenicity, as well as the side effect of polymenorrhea (more frequent menses) when used as monotherapy. Spironolactone in combination with a COC would also improve hormonal and metabolic manifestations of PCOS as well. The usual effective spironolactone dose is 50 to 100 mg orally twice daily for 6 to 12 months. Serum potassium and renal function should be monitored because this aldosterone antagonist can cause hyperkalemia. Furthermore, spironolactone should not be used with a COC containing drospirenone because of a potential risk for hyperkalemia.

Finasteride

Finasteride is a type II 5α-reductase inhibitor, which decreases the conversion of testosterone to DHT. It provides an approximate 30% reduction from baseline for hirsutism. Compared with spironolactone, finasteride is as or less effective in women with hirsutism.[66] The dose of 5 to 7.5 mg orally daily typically takes 6 months for clinical improvement. It is critical to avoid pregnancy while taking this drug owing to the potential teratogenic effect of abnormal genitalia in the male fetus. Finasteride should not be touched or handled by women who are or may be pregnant. This danger limits the usefulness of finasteride in women with PCOS because most are of childbearing age or desire pregnancy.

E.F. should be encouraged to continue her COC for at least 3 months as most COC side effects resolve within 3 months of use. If E.F. decides that the side effects from the COC are intolerable, an appropriate recommendation for E.F. would be spironolactone 50 mg orally daily. She should continue this therapy for as long as she desires the benefits of this therapy, but it will not provide contraception. E.F. should ensure proper contraception is used while taking spironolactone to avoid teratogenicity.

CASE 50-1, QUESTION 7: E.F. successfully used oral contraceptives for 7 years. After getting married 3 years ago, E.F. and her husband have decided to have children. She lost 30 lb with diet and exercise when she got married and has been able to maintain that weight loss. They have been trying to get pregnant for the last 18 months. The reason for infertility has been identified as oligo-ovulation associated with PCOS. What treatments for ovulation induction should be used in E.F. and why?

Anovulation or oligo-ovulation in women with PCOS is usually first treated with diet, exercise, and weight reduction. Weight loss improves pregnancy rates and reduces miscarriage rates in women with PCOS. E.F. has been successful at losing weight and now must consider agents for ovulation induction.

AGENTS FOR OVULATION INDUCTION

Clomiphene Citrate

Clomiphene citrate induces ovulation via an antiestrogenic effect on the hypothalamus. GnRH secretion is increased, which increases LH and FSH production. The increase in FSH concentrations causes appropriate follicle development and estrogen secretion, which produces a positive feedback on the hypothalamic–pituitary system to create a LH surge for ovulation.

The usual initial dose of clomiphene citrate is 50 mg orally daily for 5 days, started on day 5 after a spontaneous or progestin-induced menses. The clinician must determine whether ovulation occurs with each cycle through laboratory testing, ultrasound monitoring, or both. If ovulation does not occur, the dose can be increased by 50 mg orally daily up to 150 mg orally daily; however, doses greater than 100 mg orally daily for 5 days are not recommended by the manufacturers.[67] A repeat cycle can be administered as early as 30 days after the previous cycle as long as pregnancy has not occurred. If conception does not occur, women can use clomiphene for three to four cycles before considering another regimen. Long-term cyclic therapy is not recommended beyond a total of six cycles because of potential ovarian cancer risk. Most women respond to clomiphene citrate within three to four ovulatory cycles, but 5% to 10% have demonstrated clomiphene resistance and need to consider other options.[67] For women who are clomiphene citrate-resistant, dexamethasone can be used in conjunction with clomiphene or an aromatase inhibitor can be used (e.g., letrozole, anastrozole) as an alternative for infertility in PCOS.[68–71]

Aromatase Inhibitors

Letrozole is an aromatase inhibitor which blocks estrogen synthesis to directly affect hypothalamic–pituitary-—-ovarian function and increase pregnancy rates. Potential advantages of letrozole over clomiphene citrate include more physiologic hormonal stimulation of the endometrium, a lower multiple-pregnancy rate through single-follicle recruitment, a better side-effect profile with fewer vasomotor and mood symptoms, and more rapid clearance which reduces the chances of periconceptional exposure.[72] In a study of 750 women with PCOS, letrozole or clomiphene was provided for up to five cycles whereas ovulation and pregnancy were evaluated.[73] Women receiving letrozole had more live births compared with those that received clomiphene (27.5% vs. 19.1%; $p = 0.007$) without significant differences in congenital anomalies. The ovulation rate was also higher with letrozole than clomiphene (61.7% vs. 48.3%; $p < 0.001$). Letrozole had a higher incidence of fatigue and dizziness, and clomiphene had a higher incidence of hot flushes. Based on this information and its potential advantages over clomiphene, letrozole may become a first-line agent for ovulation induction in women with PCOS.

Other Agents

If the clomiphene or letrozole is not successful, dexamethasone 0.25 mg at bedtime can be used in combination with clomiphene.[74] Ovarian drilling is the next alternative, followed by administration of gonadotropins or in vitro fertilization. Ovarian drilling is a laproscopic procedure by which a small portion of the ovary is removed via electric current to reduce hyperandrogenemia and improve ovulation. Its effects may only last a few months, and it will not help with clinical signs of hyperandrogenism (e.g., hirsutism, acne). Gonadotropins are effective, but are generally reserved as one of the last options because of ovarian hyperstimulation syndrome. Egg retrieval and in vitro fertilization may be used in conjunction with gonadotropins to increase pregnancy rate and minimize the likelihood of multiple pregnancies by limiting the number of transferred embryos.[67]

Women with PCOS exhibit unique clinical features and have individual concerns that should be addressed when making treatment recommendations. Assessment should include gathering relevant medical information, such as menstrual history, signs and symptoms of hyperandrogenism, time course of symptoms, weight history, previous agents tried, and family history. If PCOS is suspected, laboratory assessments should be performed to rule out any other related disorders. Once a diagnosis has been made, a recommendation about treatment must consider the patient's priorities and motivation. For E.F., letrozole would likely be the pharmacologic agent of choice. Ovulation induction and live birth occur in approximately 48% and 27% of women with PCOS, respectively, using letrozole. The initial dose would be 2.5 mg orally once daily for 5 days, started on day 3 after a spontaneous or progestin-induced menses. If nonresponse occurs, the dose may be increased by 2.5 mg and up to 7.5 mg daily for 5 days on following cycles. Although side effects (e.g., fatigue, dizziness) can occur, the benefit of this therapy outweighs the risk for E.F. Appropriate follow-up for E.F. should include quality-of-life measures, laboratory monitoring when necessary, and medication adherence monitoring. Providers should be educators, facilitators, and empathetic listeners to help women with PCOS become informed and actively engaged in their therapy plan.

DYSMENORRHEA

Dysmenorrhea, or painful cramping that occurs with the onset and first days of menstruation, can be categorized as either primary (without underlying uterine pathology) or secondary (owing to underlying uterine pathology). Secondary dysmenorrhea can result from uterine conditions, including endometriosis, uterine polyps, or fibroids; complications of intrauterine device (IUD) use; or pelvic inflammatory disease.

Up to 93% of adolescents report some pain with menstruation, and up to 15% experience pain that is sufficiently severe and disabling to interfere with activities of daily life.[75] Dysmenorrhea is the single largest cause of lost productivity and school absence among adolescent girls. It most commonly begins within 1 to 2 years after the onset of menses, and up to 91% of adult women report some pain with menses, of which up to 28% experience severe pain and/or limitation of activity.[76]

Clinical Characteristics

CASE 50-2

QUESTION 1: A.B., a 17-year-old girl, presents at the pharmacy with complaints of severe cramping pain associated with her menstrual cycles. The pain predictably begins with the onset of menses and has been occurring for the past 5 years, but is now limiting A.B.'s ability to play sports in high school. A.B. states that she experienced her first menstrual period at age 11. The pain usually is "like a fist, clenching and relaxing," starts in the pelvic area, and radiates to her lower back. She reports no headache, but usually has diarrhea and some nausea, without vomiting. Her symptoms are most severe during the first 12 to 24 hours of her menses, then subside during the next few days. She usually takes two acetaminophen 325-mg tablets when her pain begins and then one tablet every 4 to 6 hours, as needed, with little relief. She has taken no other medications for her symptoms, has no known allergies to medications, and is not taking any other medications. She has no other medical problems. Her social history is significant for occasional social use of less than 10 cigarettes and two to three alcoholic beverages/weekend. A recent physical examination was within normal limits. What clinical manifestations in A.B. are consistent with primary dysmenorrhea?

No specific diagnostic criteria exist for primary dysmenorrhea. Typically, the diagnosis is one of exclusion and is based on response to known effective therapy. Thus, if patients do not respond to therapy, an investigation of pelvic pathology and secondary dysmenorrhea should occur.[77,78] A.B.'s symptoms that are typical of primary dysmenorrhea include cramping pain in the suprapubic area, which may radiate into the back and thighs, nausea, and diarrhea. Some women also experience vomiting, fatigue, headache, lightheadedness, flushing, loss of appetite, irritability, nervousness, and insomnia.[77] Symptom severity seems to correlate with women who have early menarche (onset of menses before age 8) and those with increased duration and quantity of menstrual flow.[79] Risk factors for dysmenorrhea include age younger than 20 years, depression or anxiety, perceived high life or work stress, nulliparity, menorrhagia, and smoking.[76,80]

Primary dysmenorrhea occurs only with ovulatory cycles, which typically begin after the first year following menarche. Dysmenorrhea occurring several years after menarche is most likely secondary dysmenorrhea and should be investigated as such. Because A.B.'s pain began within 1 year of menarche and her physical examination is normal, a trial of therapy can be initiated without further investigation into secondary causes of dysmenorrhea. The typical pattern of dysmenorrhea is to have pain beginning up to 12 hours before menses, increasing in severity for up to 24 hours, and continuing with reduced intensity for 24 to 72 hours.[77] A.B.'s description of pain, as a cramping–relaxing cycle, is typical for dysmenorrhea. Likely, her symptoms will decrease with age, after the onset of sexual activity, as well as after childbirth.[79]

Pathophysiology

CASE 50-2, QUESTION 2: What underlying pathophysiology explains A.B.'s symptoms?

In the normal menstrual cycle, prostaglandins are released by the endometrium in the late luteal phase inducing contraction of the uterine smooth muscle and subsequent sloughing of the endometrium, leading to menstrual flow and the beginning of the follicular phase of the next cycle. Women with primary dysmenorrhea appear to have increased prostaglandin secretion, inducing more intense uterine contractions, leading to decreased uterine blood flow and uterine hypoxia, which results in the cramping and pain that are the hallmarks of dysmenorrhea.[78] The decreasing levels of progesterone in the late luteal phase trigger the release of arachidonic acid from cell membranes, ultimately resulting in the production of prostaglandins and leukotrienes.[78]

The importance of prostaglandin secretion in the pathology of primary dysmenorrhea is confirmed by studies of the exogenous administration of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and PGE_2, each of which produce pain and uterine contractions similar to those observed in women with primary dysmenorrhea.[81] These prostaglandins, with potent platelet disaggregation and vasodilatory properties, also induce nausea, vomiting, and diarrhea. Thus, A.B.'s pain, nausea, and diarrhea may be caused by elevated prostaglandin levels. This also explains the rationale for the effectiveness of the two main treatments for primary dysmenorrhea: nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit prostaglandin synthesis, and hormonal contraceptives, which minimize the progesterone increase typically seen in the luteal phase.

Nearly 85% to 90% of women initially thought to have primary dysmenorrhea respond to NSAIDs with or without oral contraceptive therapy. The remaining women deserve further investigation into potential causes of secondary dysmenorrhea.[82]

Treatment

NONPHARMACOLOGIC TREATMENT

CASE 50-2, QUESTION 3: What nonpharmacologic therapies may be effective for the treatment of A.B.'s symptoms of primary dysmenorrhea?

A.B. should be educated about the causes of primary dysmenorrhea, its associated symptoms, and the rationale behind nonpharmacologic and pharmacologic treatment options. Nonpharmacologic therapies that may have benefit in the relief of A.B.'s symptoms include aerobic exercise, heat therapy, tobacco cessation, omega-3 polyunsaturated fatty acids, and high frequency transcutaneous electrical nerve stimulation.

Exercise, particularly aerobic exercise, has been correlated with decreased menstrual symptoms in observational studies and is, in all patients, associated with positive general health benefits.[83] In addition, specifically yoga exercise, in particular the cobra, cat, and fish poses performed for 20 minutes/day during the luteal phase, was found to reduce pain in adolescent women.[84] The benefit may be due to improved pelvic blood flow and decreased ischemia, or increased release of β-endorphins. Application of local heat to the lower abdomen has been studied in three well-designed clinical trials.[85–87] Heat plus ibuprofen (400 mg orally TID) demonstrated a reduction in the time to pain relief compared with an unheated patch plus ibuprofen in two controlled studies.[85,87] Heat provided better relief than acetaminophen (1,000 mg orally as a single dose).[85] With few adverse effects, heat, in the form of a heating pad or heated patch or wrap device; and exercise (aerobic or yoga) represent reasonable and safe suggestions for women with dysmenorrhea.

Women should be advised and assisted in efforts to stop tobacco use. Although no direct evidence links smoking cessation with improvement in dysmenorrhea, an association exists with increased risk and severity of dysmenorrhea in women who

smoke.[79] Increased intake of omega-3 polyunsaturated fatty acids, a low-fat vegetarian diet, or both may decrease the intensity and duration of symptoms.[88,89]

A.B.'s therapy should be based on her specific symptoms, response to previous therapy, and any adverse effects of therapy. The regimen of acetaminophen that A.B. is currently using is not providing relief owing to its relative lack of effect on prostaglandin activity. For A.B., discussion of the nonpharmacologic therapies, particularly continuous low-level heat applied at onset of symptoms, exercise/yoga, and smoking cessation, provides low-risk, potentially beneficial, and low-cost suggestions for pain relief, in addition to drug therapy. A.B should be informed that continuous heat therapy via heat "wraps" or hot water bottle or heating pad should be used cautiously in patients with diabetes and should not be used while sleeping.

CASE 50-2, QUESTION 4: A.B states that her pain is decreased about 50% with the use of a heating pad, but she would rather not be sedentary for hours at a time. She finds the heat wraps uncomfortable and expensive and asks about Pamprin. What are some over-the-counter pharmacologic options for A.B.?

Although nonpharmacologic therapy with heat, exercise, and smoking cessation may have benefit, often the use of pharmacologic therapies is required to significantly improve functionality.

OVER-THE-COUNTER PHARMACOLOGIC THERAPY

Over-the-counter (OTC) pharmacologic therapy for primary dysmenorrhea is focused on reducing prostaglandin activity. Anti-inflammatory drugs act by directly inhibiting prostaglandin synthesis. NSAIDs provide relief from the symptoms of primary dysmenorrhea for most women (See Case 50-2, Question 5, for further information). Naproxen (as the sodium salt) and ibuprofen are approved without a prescription for the treatment of primary dysmenorrhea. Acetaminophen is of limited efficacy in the treatment of dysmenorrhea when compared with NSAIDs or hormonal contraception.[90]

Other therapies, including OTC products marketed for dysmenorrhea and other menstrual disorders (e.g., Pamprin, Midol) (particularly combination products including diuretics), weak muscle relaxants (such as pyrilamine, pamabrom), diuretics (caffeine), and acetaminophen, have limited efficacy for the specific treatment of dysmenorrhea. Because they do not address the underlying pathophysiology of primary dysmenorrhea, combination products, narcotic analgesics, and acetaminophen do not have a role in the treatment of primary dysmenorrhea and may have excessive adverse effects with minimal benefit.

Adolescents with dysmenorrhea frequently use OTC medications to treat primary dysmenorrhea, usually without consultation from a healthcare professional. This lack of professional advice results in the use of lower doses that may not be as effective to treat symptoms. Many women choose ineffective combination medications and/or acetaminophen, indicating patients will benefit from professional advice regarding OTC treatments of dysmenorrhea. Other products include vitamin B_1, vitamin D, magnesium, vitamin B_6, and omega-3 fatty acids, which have all shown some benefit in pain relief compared with placebo, with vitamin D, vitamin $B_{1,}$ and magnesium showing the most promise.[89,91] Other dietary supplements, including fennel, vitamin E, Neptune Krill Oil, and Toki-shakuyaju-san, have been evaluated in small trials and need further study.[82] At this point, given the limited efficacy of non-NSAID, nonhormonal methods of treatment, they are not an appropriate alternative for A.B. Ibuprofen 200 to 400 mg orally up to TID could be a solid initial plan for A.B.'s menstrual cramps.

Prescription Pharmacologic Agents: Nonsteroidal Anti-inflammatory Drugs

CASE 50-2, QUESTION 5: A.B has tried OTC ibuprofen 400 mg TID starting at onset of her cramping symptoms, but has not had optimal relief. A.B. presents to her family physician for an evaluation. What prescription medications could be recommended for A.B's dysmenorrhea?

The NSAIDs are effective for treatment of dysmenorrhea, but in some cases, OTC doses are not enough and prescription-strength NSAIDs or hormonal contraceptives may be required for adequate relief. Hormonal contraceptives reduce the amount of endometrial proliferation and, as a result, decrease the amount of prostaglandins secreted. By inhibiting ovulation, hormonal contraceptives eliminate the cyclic changes in progesterone that induce prostaglandin release. Choice of therapy depends on the need for contraception, concomitant medical conditions, and patient preference. Treatment efficacy can be monitored by evaluating pain relief, improved functionality, reduced absenteeism, and relief of other symptoms (e.g., diarrhea, nausea) associated with dysmenorrhea. Because A.B. is not sexually active, prescription-strength NSAIDs should be tried for two to three cycles before switching to other agents.

Initial selection of NSAID therapy should be based on effectiveness, incidence of adverse effects, cost, patient history of previous benefit, and availability. In a Cochrane review, 73 trials of NSAIDs for treatment of primary dysmenorrhea were reviewed to assess for any differences in efficacy or safety among the different NSAIDs.[92] When compared with placebo, NSAIDs were significantly more effective (odds ratio [OR], 4.50; 95% confidence interval [CI], 3.85–5.27). When compared with acetaminophen, NSAIDs were, as expected, significantly better at reducing symptoms (OR, 1.90; 95% CI, 1.05–3.44). In limited head-to-head trials comparing NSAIDs, no significant differences in efficacy were seen, with the exception of aspirin being slightly less effective than other NSAIDs when directly compared. Adverse effects seen in these trials were generally mild GI (nausea, upset stomach) and neurologic (sleepiness, dizziness, headache) complaints. When directly compared with each other, no NSAID was found to be better tolerated than another. Naproxen offers the advantage of less frequent dosing compared with ibuprofen.

Some data suggest that an oral loading dose of naproxen sodium (550 mg) might improve pain control in dysmenorrhea. A randomized trial demonstrated increased relief from dysmenorrhea symptoms in adolescents treated with an NSAID regimen that started with a loading dose, versus those who used a flat dosing regimen.[93] Loading doses generally are twice the regular dose. If A.B. experienced adverse effects with the higher loading dose, an alternative strategy is to initiate dosing 24 hours before menses is expected to start, based on the calendar if the patient has predictable cycles, or based on the start of premenstrual syndrome-type symptoms. This prophylactic dosing may be helpful especially for patients who have severe dysmenorrhea with absenteeism and decreased work or school productivity.[78,92] Although no specific evidence supports the use of scheduled NSAID dosing regimens, avoiding as-needed dosing may provide consistent serum levels to maintain reduced prostaglandin levels. As the duration of therapy is typically limited to 2 or 3 days, risk of adverse effects tends to be outweighed by the potential benefit of loading doses, prophylactic dosing, and scheduled versus PRN therapy.

A good recommendation for A.B. could include initiating naproxen sodium 550 mg orally at the beginning of menses, followed by 275 mg every 8 hours thereafter for the 2 to 3 days she experiences dysmenorrhea.

Adverse Effects

CASE 50-2, QUESTION 6: What adverse effects might A.B. experience from her NSAID?

All NSAIDs have a similar adverse effect profile. Nausea, vomiting, indigestion, anorexia, diarrhea, constipation, abdominal pain, melena, and bloating are common GI complaints.

Careful attention should be given to previous trials of NSAIDs for dysmenorrhea and other conditions, because women may respond favorably to one NSAID over another. If a 2-month or 3-month trial at appropriate doses of one NSAID is unsuccessful for A.B., another agent from a different chemical class may be tried. Because dysmenorrhea is most prevalent in younger women who tend to be healthy, the risk of adverse events may be lower than would be expected in an older population.

Contraindications

CASE 50-2, QUESTION 7: What medical history information is important to avoid serious adverse effects?

A.B should be questioned about medication allergies and any prior history of ulceration or GI bleeding; a history of cardiovascular and renal disease, although uncommon in young women, should be elicited before prescribing therapy. A thorough medication history, including OTC agents and dietary supplements, should be conducted. Particular attention should be paid to any potential therapeutic duplications (e.g., prescription and OTC NSAIDs), drug–drug interaction (e.g., warfarin), and drug–disease (hypertension) interaction.

Women who are allergic to aspirin or have a history of allergic reaction to any NSAID should not use NSAIDs or celecoxib. A.B. has not had a previous allergic reaction to NSAID or aspirin; she is not taking any medications that may interact and does not have any history of medical problems that would prevent her from a trial of NSAID therapy.

Hormonal Contraception

Oral Contraceptives

CASE 50-2, QUESTION 8: After 6 months of treatment, A.B. has some relief of her pain, nausea, and diarrhea with the naproxen sodium, but is unhappy with the amount of time that she is spending at home due to menstrual cramps. She is asking about other treatment options for further pain relief. What other options are available for A.B.?

As mentioned previously, hormonal contraceptives may be an option in A.B. if prescription NSAIDs are not adequate for her symptoms. Oral contraceptives (OCs) suppress ovulation, decrease menstrual fluid volume, and subsequently decrease prostaglandin production and uterine cramping.[75,77] OCs alone, or in combination with an NSAID, are appropriate as first-line treatment in women with or without a need for contraception.[94] OCs relieve dysmenorrhea symptoms in 50% to 80% of women within 3 to 6 months after beginning hormone therapy.[95] A study of healthy adolescent women with primary dysmenorrhea evaluated the effects of a 20 mcg ethinyl estradiol/100 mcg levonorgestrel oral contraceptive pill as compared with placebo during a 3-month period.[96] With OC use, women reported decreased severity of pain and used less pain medication. A Cochrane review of oral contraceptives and primary dysmenorrhea found oral contraceptives containing less than 35 mcg of ethinyl estradiol to be effective at reducing pain, but failed to demonstrate a significant difference between various 35-mcg ethinyl estradiol OC formulations.[95] Selection of an OC should be based on factors presented in Chapter 47, Contraception. A randomized controlled trial has evaluated the use of continuous dosing of oral contraceptives compared to the traditional 21 active days, 7 placebo days regimen, with an initial benefit in favor of decreased pain in the continuous dosing group at 1 and 3 months that was lost after 6 months of use.[97]

Adverse effects and contraindications associated with OC use must be considered (See Chapter 47, Contraception). Although serious complications from OC use are uncommon in young, healthy women, breakthrough bleeding and spotting, nausea, and breast tenderness may occur, especially early in treatment. A.B. may choose to add an OC to her naproxen sodium, with potentially improved pain relief compared with either agent alone. If pain does not respond to either course of therapy, investigation via laparoscopy for causes of secondary dysmenorrhea may be necessary.

Other Hormonal Contraceptive Agents

Other hormonal contraceptive agents that suppress ovulation have also been used in the treatment of primary dysmenorrhea, although none have undergone rigorous trials for this indication.[82] The levonorgestrel intrauterine system (IUS) is associated with amenorrhea and a reduction in dysmenorrhea over time, unlike the copper IUD, which may result in increased pain, cramping, and blood loss. Three years after insertion, fewer women with a levonorgestrel IUS reported menstrual pain (60% baseline, 29% after 3 years), with 47% of women with amenorrhea.[98] In women with primary dysmenorrhea at low risk of sexually transmitted infections, and desiring long-term contraception, the levonorgestrel IUS would be a reasonable option.

Medroxyprogesterone depot injection is another hormonal contraceptive agent that has been used to treat primary dysmenorrhea. Nearly two-thirds of adolescents reported fewer symptoms of dysmenorrhea with injections every 3 months.[77] Negative effects of medroxyprogesterone injections on bone density should be weighed with potential benefit when considering this option (See Chapter 47, Contraception). Given that A.B.'s past history does not include any absolute contraindications to combined oral contraceptives and her dysmenorrhea symptoms have not been well controlled with prescription NSAIDs, she is a candidate for combined hormonal contraception. A trial of combined oral contraceptives would be an appropriate plan for better control of her dysmenorrhea. In addition to smoking cessation, she should be counseled that hormonal contraceptives may require 3 or more months to provide maximal relief of symptoms. The goals of therapy, namely reduction in pain and associated symptoms, as well as improvement in functionality, should be explained to A.B. and reviewed at each contact.

ENDOMETRIOSIS

Endometriosis is defined as the presence of functional endometrial tissue occurring outside the uterine cavity. It is the most common cause of secondary dysmenorrhea in young women and can result in chronic pelvic pain, infertility, and dyspareunia.[77] The ovaries are commonly the site of endometriosis, which can also be found in the pelvic peritoneum, cervix, vagina, vulva, rectosigmoid colon, and appendix.

Less common sites of implantation of endometrial tissue include the umbilicus, scar tissue resulting from surgery, kidneys, lungs, and even arms and legs.[99] Endometriosis is present in up to 45% of women with infertility. Overall, it is difficult to determine the prevalence of endometriosis, because many women do not

---

experience symptoms or seek treatment, and formal diagnostic criteria currently require visual identification of endometrial tissue during surgery. In women who have laparotomies for any reason, endometriosis is identified in 5% to 15%. This increases to 33% in women with chronic pelvic pain.[99] In contrast to primary dysmenorrhea, endometriosis usually occurs in women who have been menstruating for some time; it can provoke pain that is not limited to the time of the menses, but can occur anytime throughout the cycle. Endometriosis is rarely seen in women near the menarche, after menopause, or in amenorrheic women. The average age at diagnosis is 36.4 years, and even before diagnosis, women with endometriosis have higher healthcare costs and utilization, particularly emergency room utilization, than age-matched controls.[100]

Diagnostic Criteria

Diagnosis of endometriosis is difficult, with a delay in diagnosis in the range of 8 to 12 years from initial symptom presentation.[101] Endometriosis, interstitial cystitis, irritable bowel syndrome, and pelvic adhesions represent the four most common causes of chronic pelvic pain (defined as pain not associated with the menses, severe in nature, resulting in functional disability, and lasting at least 6 months).[102] The delay in diagnosis is the unfortunate consequence of the lack of diagnostic laboratory markers and its similarities to these other conditions. The physical examination is often normal, although the most common physical finding is a fixed retroverted uterus, with scarring and tenderness. A definitive diagnosis is only possible with visualization of endometriosis on laparoscopy, although this is not considered as absolutely necessary today as it has been in the past.[103] Although no diagnostic criteria currently exist, endometriosis can be staged at the time of laparoscopy according to the Revised American Fertility Society Classification of Endometriosis.[104] The stages are classified as minimal (stage I), mild (stage II), moderate (stage III), and severe (stage IV), as determined by an accumulated point total, with points based on the location of the endometrial lesions, the size of the lesions, the presence and extent of the adhesions, and the degree of obliteration of the posterior cul-de-sac. The classification system is designed to document the location and extent of endometriosis, does not predict infertility, aid in treatment selection or outcomes, or predict recurrence of disease. Making diagnosis and prognosis more difficult is that the reported severity of pelvic pain and level of functional disability do not seem to be correlated with the stage of endometriosis.[99]

Pathophysiology

Although the first description of endometriosis was made in the 1860s, the precise etiology of endometriosis remains a mystery. Several theories exist regarding the origins of endometriosis, and the exact etiology is probably a complex interplay between physical and individual patient-specific immunologic factors.[99]

The most commonly cited theory is that of retrograde menstruation or the flow of menstrual fluid, endometrial cells, and other debris backward through the fallopian tubes resulting in implantation in the peritoneal cavity. Once endometrial cells reach the peritoneum, stimulated angiogenesis (potentially by estrogen, among other factors) appears to be a determinant of the development and growth of lesions.[105,106] Also at this point, the lesion stimulates an immune response, triggering the activation of macrophages, as well as cytokine and growth factor release. Peritoneal lesions may contribute to more distant disease by spread via hematogenous or lymphatic routes, or even by movement owing to iatrogenic causes, such as cesarean sections and other forms of gynecologic surgery. Although the retrograde menstruation theory makes scientific sense, it has been discovered that retrograde menstruation occurs in nearly all menstruating women (90%) and not all women have endometriosis. This suggests that an additional factor, such as genetic susceptibility or altered immunity, or altered hormone receptor functioning such as progesterone resistance, must be present for the pathogenesis of endometriosis in certain patients.[107]

Another theory for the etiology of endometriosis is the coelomic metaplasia theory. This theory rests on the belief that the coelomic epithelium, the fetal originator tissue for the reproductive tract, retains its ability to differentiate into multiple cell types.[99,107,108] The trigger for differentiation is thought to be, in part, estrogen or environmental factors. This theory would explain the presence of endometriosis in prepubertal girls, in women born without a uterus, and in the rare cases of endometriosis seen in men. Genetics also play a role in the development of endometriosis. For first-degree relatives of women with severe endometriosis, there is a 6 times higher rate of developing endometriosis when compared with women who do not have affected relatives. These woman also have more severe disease and disease that appears earlier in life.[101,109] More than 15 different gene and gene product abnormalities have been documented in women with endometriosis. Environmental factors, as discussed, are intriguing in their role as potential causative factors, but are not definitive.[107,109]

Once endometrial tissue becomes implanted, hormones are necessary for their continued growth. As with intrauterine endometrium, the implants of endometriosis possess estrogen, progesterone, and androgen receptors. The endometrial implants may, however, respond differently to hormonal stimulation than normal endometrium. In general, estrogens stimulate the implants, whereas androgens or lack of estrogen results in implant atrophy. Because of their complex hormonal effects, progestins have variable effects on the implants.[104,107,110] In addition, lesions also show high levels of estrogen biosynthesis, owing to abnormally increased aromatase activity, with a concomitant decrease in the inactivation of estrogen, resulting in high intralesional estrogen concentrations.[107,111] The responsiveness of endometrial implants to ovarian hormones plays a role in the pathology of endometriosis. Withdrawal of estrogen and progesterone causes the endometrial implants to bleed, leading to an inflammatory response in the adjacent tissues. Repetitive cycles of bleeding and inflammation lead to the development of scar tissue and adhesions between adjacent peritoneal tissues. On laparoscopy, these areas of involvement appear as multiple hemorrhagic foci composed of endometrial epithelium, stroma, and glands. Ovarian endometriosis usually involves the formation of endometriomas, blood-filled cysts (chocolate cysts) ranging in size from microscopic to 10 cm. Nodules may form on uterosacral ligaments. Fibrosis usually is present with the endometrial implants, and extensive adhesions may form between pelvic structures.[112]

Clinical Characteristics

CASE 50-3

QUESTION 1: N.H. is a 32-year-old woman who has been married for 6 years and is currently using the vaginal contraceptive ring to prevent pregnancy. She and her spouse have been contemplating the timing of a pregnancy, but have not yet attempted to become pregnant. She presents to her gynecologist to discuss preconceptual planning and reports that she has been having severe lower-abdominal cramps, associated with her menses, occurring on day 1 and lasting until day 4 or 5. This has been occurring for the past 4 years after many years of pain-free cycles and has recently been increasing in severity. The pain is slightly relieved by ibuprofen 400 mg orally TID, and during the past 6 months she has had to work from home at least 1 to 2 days/month owing to pain that has been increasing in frequency. On further questioning, she also reports mild-to-moderate pain that occurs randomly in her cycle, associated with low back pain, constipation with painful defecation, and pain with intercourse. Her menstrual history reveals menarche at age 10 with regular cycles every 26 to 27 days and heavy menses for 6 to 7 days. She reports discussing her symptoms with her mother, who described similar symptoms during her childbearing years.

N.H. is 5 feet 7 inches and weighs 145 lb. She smokes one-half pack of cigarettes/day and does not drink alcohol. She plays recreation league basketball and softball, but does not have a regular exercise regimen. She usually eats five servings of fruits or vegetables per day, but does not like to drink milk. She is concerned about her heart because her father had a cardiac stent placed at age 40, and she has been told she has high cholesterol.

Her physical examination is normal, with the exception of tenderness on palpation of the posterior fornix and a fixed retroverted uterus. A pregnancy test and tests for gonorrhea and chlamydia are negative, and a Pap smear is within normal limits. What subjective and objective data in N.H.'s presentation are compatible with a diagnosis of endometriosis?

A woman presenting with endometriosis may have signs and symptoms that are difficult, initially, to distinguish from primary dysmenorrhea[113] (Table 50-2). N.H.'s symptoms of lower abdominal cramps accompanying her menses are often mistaken for primary dysmenorrhea when other history details are not evaluated in total. N.H.'s age and her nulliparity are consistent with the characteristics of women with endometriosis. Although endometriosis has been diagnosed in women of all ages, it most commonly occurs in women in their late 20s and early 30s who have delayed pregnancy or who have infrequent pregnancies.

N.H.'s menstrual pattern of short cycle length with prolonged flow is characteristic of women with endometriosis. Risk factors for endometriosis are related to exposure to estrogen (i.e., early menarche and late menopause), and shorter menstrual cycle length (<28 days) with longer duration of menstrual flow (≥6 days), as well as having a mother or sister with endometriosis, as may be true with N.H.'s mother.[114] Women who have four or more pregnancies lasting greater than 6 months have a 50% lower risk of being diagnosed with endometriosis, and there is a decrease in risk of endometriosis that is parallel to duration of time spent in breastfeeding.[114] Higher BMI and shorter stature are associated with a lower risk of endometriosis, with a 12% to 14% decreased likelihood of diagnosis for every unit (kg/m^2) increase in BMI.[114] Potential, but not yet confirmed, risk factors that have been identified include higher social class, exposure to dioxins, and intake of caffeine and alcohol.[114] Cigarette smoking appears to reduce the risk for endometriosis, although studies are not conclusive.[108,109] Women with several immune-mediated conditions, including rheumatoid arthritis, systemic lupus erythematosus, hypothyroidism and hyperthyroidism, and multiple sclerosis, also have a higher rate of endometriosis than women without these immune-medicated conditions.[114]

Table 50-2

Primary versus Secondary Dysmenorrhea

Characteristic	Primary Dysmenorrhea	Secondary Dysmenorrhea
Onset	Around menarche	Any age (while menstruating)
Timing in menstrual cycle	Worse on day 1, lasts 24–48 hours	Increases in severity, may last days
Change over time	Stable, predictable	Increasing pain with increasing age
Symptoms	Low back pain, premenstrual syndrome, nausea, bloating	Low back pain, dyspareunia, diarrhea or constipation, dysuria, infertility
Signs	Normal pelvic examination	Fixed retroverted uterus, tenderness, but may be completely normal

Source: Reddish S. Dysmenorrhea. Aust Fam Physician. 2006;35:82.

Table 50-3

Location of Endometriosis and Associated Symptoms

Sites	Symptoms
Pelvic	
Cervix	Abnormal uterine bleeding
Ovaries	Dysmenorrhea
Peritoneum	Dyspareunia
Rectovaginal septum	Infertility
Uterosacral ligaments	Pelvic pain
Intestinal	
Abdominal scars	Intestinal obstruction
Sigmoid colon	Mid-abdominal pain
Small intestines	Nausea
	Painful defecation
	Rectal bleeding
Urinary Tract	
Bladder	Cyclic flank pain
Ureter	Hematuria
	Hydronephrosis
	Hydroureter

Source: American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 114. Management of endometriosis. Obstet Gynecol. 2010;116:223.

N.H.'s chief complaints center on her progressive pelvic pain occurring throughout the cycle, with worsening during menses, constipation, and pain with intercourse (dyspareunia). Women who report pain during intercourse may have a fixed, retroverted uterus (as N.H. does) or endometriosis located in the posterior fornix of the vagina or along the uterosacral ligaments.[99] This pain may persist for several hours after intercourse. Other symptoms such as the constipation and painful defecation N.H. is experiencing are associated with endometriosis and may (but not always) depend on the organs affected by the location of the endometrial tissue[115,116] (Table 50-3). Depression also is a common symptom in patients with endometriosis, particularly those with chronic

pelvic pain, and may express as sadness, somatic complaints, and inability to work or carry on activities of normal living.[117]

Although it is unclear yet whether infertility will be a problem in N.H., endometriosis occurs in up to 45% of women with infertility.[99] The cause of endometriosis-associated infertility is not clear, but is probably caused by a combination of factors, which may include physical distortion of the pelvic architecture, inflammatory factors (including prostanoids, cytokines, and growth factors that may interfere with normal reproductive processes), impaired folliculogenesis (follicle development), or defects in fertilization or implantation.[118,119] Treatment for endometriosis, in inducing a "pseudomenopause," results in impaired fertility while the disease is actively being treated.

N.H.'s limited physical findings are not uncommon in women with endometriosis; physical findings, other than visualization of endometrial tissue during exploratory surgery, may not be present, and outward physical findings may have no correlation with the stage of endometriosis determined with surgery. Many symptoms and physical findings of endometriosis can be associated with other gynecologic conditions or diseases (particularly irritable bowel syndrome), and, if the patient is not responsive to empiric therapy, laparoscopy is indicated to confirm the diagnosis. N.H.'s negative pregnancy, chlamydia, and gonorrhea tests, as well as her normal Pap smear, are reassuring. The CA-125 laboratory test is not sufficiently sensitive or specific enough as a single test to diagnose endometriosis, and while many biomarkers are being studied, none have demonstrated sufficient sensitivity and specificity to be clinically useful.[120]

Treatment

CASE 50-3, QUESTION 2: N.H.'s pain is uncontrolled after trials of three different NSAIDs (ibuprofen, naproxen, and meloxicam), and she would like relief to improve her functionality at work and home. Given the potential mechanisms behind the pathophysiology of endometriosis, what therapeutic approaches are appropriate for the treatment of endometriosis in N.H.?

Therapy for endometriosis should be individualized and should consider N.H.'s desire for future fertility, severity of symptoms, extent of disease, and potential for infertility. This should be done with the knowledge that a high likelihood exists of recurrence and a lack of good prognostic indicators for future severity. The goals of treatment are to relieve symptoms and, if desired, to preserve or improve fertility. Options currently available to treat endometriosis include definitive and conservative surgery, hormonal therapy with estrogen–progestin combinations or progestins alone, danazol, aromatase inhibitors, or the GnRH agonists, and expectant management. Pharmacologic treatment of endometriosis is based on manipulation of this hormonal response: Danazol, GnRH agonists, progestins, aromatase inhibitors, and estrogen–progestin combination all result in endometrial tissue atrophy. No treatment has been shown to provide 100% protection against recurrence when discontinued; even surgical removal of the uterus and ovaries is associated with recurrence rates of up to 10%.[106] Limited evidence-based guidelines for treatment are available and are generally limited by the poor quality of evidence and limited depth of evidence for most treatments, especially those that are emerging.[121]

PAIN MANAGEMENT: PHARMACOLOGIC THERAPY

Nonsteroidal Anti-inflammatory Drugs

NSAIDs, particularly those available as OTC products, are often the first medications that women try for relief of pain from endometriosis, often before they are officially diagnosed. NSAIDs may provide some relief of mild symptoms, particularly in women with endometriosis who have pain associated with the menses (see Dysmenorrhea section), and are an appropriate first choice for women with mild symptoms who do not desire contraception. They should not be the only therapy offered to patients with confirmed endometriosis.[122] Clinicians should be aware of and consider the potential for endometriosis in patients with noncyclic pain, including pain that does not respond to an appropriate trial of an NSAID. N.H. has tried three different NSAIDS with limited relief; a higher dose or trial of another NSAID is not an appropriate strategy at this time. Additional treatment should be considered.

Combined Hormonal Contraceptives

For women who do not receive pain relief from a trial of an NSAID, a reasonable next step for those women desiring contraception is the use of oral contraceptives because they are considerably better tolerated over the long-term versus other hormonal options. They may be used alone or in combination with NSAIDs. OCs improve symptoms of endometriosis by inhibiting ovulation, decreasing hormone levels, and reducing menstrual flow, potentially to the point of amenorrhea. These mechanisms contribute to atrophy of endometrial implants. When used, the most appropriate regimen is continuous OC dosing, so that there is not a "placebo week" that allows for growth of endometrial implants. In a trial of patients who did not respond to cyclic OCs, use of continuous dosing resulted in significant pain reduction.[123,124] A Cochrane review found that the pain reduction seen with OCs (≤35 mcg of ethinyl estradiol) is similar to a GnRH analog (goserelin).[122] After surgery, continuous regimens appear to provide better pain symptom control than cyclic regiments.[125]

Progestins

Similar to oral contraceptives, injectable progestins reduce symptoms of endometriosis by inhibiting ovulation, reducing hormone levels, and inducing endometrial atrophy. They may be particularly useful if estrogen use is contraindicated. Regimens used include oral medroxyprogesterone, depot medroxyprogesterone (see Case 50-3, Question 5), or the levonorgestrel IUS. More recent studies have evaluated the use of the levonorgestrel IUS as a means of providing consistent progestin dosing. The IUS has the advantage of providing longer-term contraception. When compared with leuprolide depot (a GnRH agonist), the levonorgestrel IUS provided similar benefits in reducing pelvic pain, with a decreased potential for hypoestrogenic effects, and an increased potential for early breakthrough bleeding, followed by eventual amenorrhea.[126]

A 3-year direct comparison of the levonorgestrel IUS versus depot medroxyprogesterone was conducted in patients with moderate-to-severe endometriosis for medical control of symptoms after conservative surgery.[127] Although symptoms were improved with both regimens, more IUS patients remained adherent to the regimen, and at 3 years, bone density was increased in the IUS group and decreased in the depot group.

Progestins, despite being as effective as GnRH agonists in the treatment of pain, have increased side effects when compared with OCs, primarily weight gain (particularly with the depot formulation), initial breakthrough bleeding followed by amenorrhea, and, with depot formulations, decreased bone density with prolonged use, placing them after combined hormonal contraception in choice of therapy.[128]

Gonadotropin-Releasing Hormone Agonists

GnRH agonists induce a pseudomenopausal state, resulting in relief of endometriosis symptoms. Because the GnRH agonists have a longer half-life than endogenous GnRH, their binding to GnRH receptors in the pituitary results in downregulation of the hypothalamic–pituitary–ovarian axis, decreasing release of FSH and LH, leading to low estrogen levels and amenorrhea.[129] GnRH agonists are available in a variety of dosage forms, outlined in Table 50-4. When compared in clinical trials, GnRH agonists have efficacy that is similar to oral contraceptives, progestins, and danazol, but their increased cost and adverse effect profile (including menopausal-type symptoms and decreased bone density) make them second-line agents, after OCs and progestins.[129]

Table 50-4

Gonadotropin-Releasing Hormone Agonists

GnRH Agonist (Brand Name)	Strength	Dosage Form	Dosage Regimen
Nafarelin (Synarel)	2 mg/mL delivers 200 mcg/spray	Intranasal	200–800 mcg BID
Leuprolide (Lupron)	3.75 mg, 11.25 mg	IM depot	3.75 mg/month or 11.25 mg every 3 months
Goserelin (Zoladex)	3.6 mg, 10.8 mg	SC implant	3.6 mg implant every month or 10. 8 mg implant every 3 months

BID, 2 times daily; GnRH, gonadotropin-releasing hormone; IM, intramuscular; SC, subcutaneous.

Aromatase Inhibitors

The most recently studied therapy for endometriosis, aromatase inhibitors (AIs), was originally developed for use in patients with breast cancer. Aromatase, the enzyme responsible for the synthesis of estrogens, is required for the conversion of androstenedione and testosterone to estrone and estradiol.[130] Although AIs, OCs, progestins, and GnRH agonists all decrease serum levels of estrogen, only AIs decrease secretion and production of estrogen by endometrial tissue itself. Anastrozole and letrozole are type II AIs, binding reversibly to the enzyme to produce a beneficial effect on endometriosis symptoms.[130] Although AIs effectively decrease estrogen conversion in the periphery, addition of an agent to reduce ovarian estrogen levels is also necessary in premenopausal women; hence, most of the studies in this population have included double therapy with AIs and oral contraceptives or GnRH analog. AIs may be used alone in postmenopausal women.[130]

Although the end result of GnRH agonists and AIs is similar, the adverse effects of the AIs are decreased, with fewer hot flashes, and primarily mild headache, nausea, and diarrhea. Although few long-term trials have been conducted, decreased bone density is suspected with the use of AIs and estrogen add-back therapy is appropriate (described later in this section and Case 50-4, Question 1). All AI studies, although small, have demonstrated reduction in pain and reduced lesion size. The largest study to date used a combination of anastrozole with GnRH agonists compared with GnRH agonists alone in patients after surgery.[131] Although effective at controlling pain, the combination resulted in significantly more bone loss than either regimen alone at 6 months, but no difference was seen at the 2-year follow-up.[131] Further research is needed to determine the role of AIs in the treatment of endometriosis, because currently they do not have an FDA indication for the treatment of endometriosis. Their use should be reserved at this time for those patients with severe endometriosis who have failed other therapies.

Danazol

Danazol, an androgenic drug derived from 17-ethinyl testosterone, also induces a pseudomenopausal state by increasing androgen levels and decreasing estrogen levels. It inhibits the enzymes involved in ovarian steroidogenesis and increases the metabolic clearance of estradiol. By creating a hypoestrogenic, hypoprogestogenic state, danazol causes anovulation, amenorrhea, and atrophy of endometrial implants. Although effective at decreasing pelvic pain, danazol is poorly tolerated because of its significant side effects, which include weight gain, voice changes, edema, acne, hot flashes, vaginal dryness, hirsutism, liver disease, and increased cholesterol; these occur in up to 85% of treated patients.[106] Because of safety concerns, use should be limited to 6 months at a time and should only be initiated in women after all other therapy options have failed.

Emerging Agents

Two new medication classes hold promise for the treatment of endometriosis, with the hope of decreased side effects when compared with current therapy. HMG-CoA reductase inhibitors (Statins) have been studied in one small clinical trial in comparison with a GnRH analog and were found to have similar efficacy in providing pain relief.[132] Further investigation needs to be done with these agents particularly in women who wish to retain the option of fertility.

An additional emerging group of therapeutic agents is the GnRH antagonists, thought to maintain the beneficial effects on pain control in endometriosis, but with decreased side effects. When compared to depot medroxyprogesterone, the first agent in this class studied for endometriosis, elagolix, (a once-daily oral medication) demonstrated noninferiority in its effects on pain control, with little effect on bone density.[133]

PAIN MANAGEMENT: NONPHARMACOLOGIC THERAPY

Definitive Surgery

Definitive surgery, referring to total abdominal hysterectomy, bilateral salpingo-oophorectomy, and removal of all visible endometriosis, theoretically should eliminate the risk of recurrence of the disease. These procedures are not an option for many women with endometriosis who desire pregnancy in the future. It is invasive surgery, reserved for those patients whose pain is unresponsive to other therapies or to conservative surgery. Furthermore, removal of all endometriosis is difficult, and recurring pain is not uncommon. Sinaii et al. surveyed patients with endometriosis regarding treatments and benefits, and found that, of the 1,160 women surveyed, 12% had had definitive surgery, with 40% reporting the surgery was successful, 33% reporting partial benefit, 5.6% reporting no benefit, and 6% of patients actually reported increased pain and symptoms after surgery.[134]

Conservative Surgery

In contrast to definitive surgery, conservative surgery (involving ablation and removal of implants, and lysis of adhesions) preserves fertility and is commonly conducted during the initial diagnostic laparoscopy. In the Sinaii et al. survey, 70% of patients had undergone laparoscopy with removal of lesions, with 30% considering the procedure a success, 50% reporting partial benefit, 15% with no difference in symptoms, and 10% reporting increased symptoms.[134] On average, women reported having three surgical procedures.[134] Drug treatment is used after conservative surgery, because it is not possible to remove all lesions, many of which are difficult to visualize.

Clinical trials in endometriosis have not singled out one treatment as the treatment of choice for all women, with most investigations demonstrating equivalence of the studied therapies. An NSAID and combined hormonal contraception (e.g., N.H.'s contraceptive vaginal ring) are the drugs of choice for initial management, owing to their safety profile and, in this case, the contraceptive agent's dual utility in preventing conception. As a next step, progestins, GnRH agonists, and AIs are options. Because of adverse effects and poor tolerability, danazol should be reserved as an agent of last choice. If N.H. were uninterested in having children in the future, surgical sterilization would be an option. Conservative surgery, including removal of endometriomas and adhesions and ablation of visible lesions, is not curative, but may provide pain relief in 50% to 95% of patients at 1 year.[129] A combination of conservative surgery, followed by postoperative progestin, combined hormonal contraceptive, GnRH agonists, or danazol, has been shown to prolong the duration of pain relief and decrease recurrence after surgery.[129]

CASE 50-3, QUESTION 3: N.H. has not had a problem in the past tolerating a variety of contraceptive products, but does have some problems with daily medication adherence, and would like to avoid giving herself injections if possible. How does this information assist in the selection of therapy for her endometriosis?

N.H. is a smoker, with poor calcium intake and some cardiovascular risk factors (family history, high cholesterol), who would rather avoid injectable medication and has trouble with daily medication taking. Danazol, with its ability to increase cardiovascular risk factors and extensive side effects, is not a good option. Although some GnRH analogs are available as nasal sprays or injectable implants, the significant risk of decreased bone density and menopause-like adverse effects place them as a second-line option. Progestins, particularly the long-acting progestins, either in the form of the medroxyprogesterone acetate 3-month depot or subcutaneous injection, or the levonorgestrel IUS, make these appropriate first-line options for N.H., although the risk of diminished bone density with depot formulations remains an issue.

CASE 50-3, QUESTION 4: N.H. would like to start the levonorgestrel IUS, but her insurance company will not pay for it to be used in the treatment of endometriosis because of its lack of FDA indication. She decides to start depot medroxyprogesterone acetate. What information can you provide her regarding use, and the benefits and risks of treatment?

Depot medroxyprogesterone acetate (DMPA) is available in two dosage forms: 150 mg to be given intramuscularly (IM) every 3 months and a 104-mg formulation given subcutaneously (SC) every 3 months. Product choice may be based on insurance coverage or potential for the patient to self-administer (the SC product may be more patient-friendly). Because N.H. does not want to self-inject, either choice, administered by her provider's office, or a pharmacist if law allows, would be an appropriate option. Although the DMPA does provide the contraception N.H. desires, she should be informed that it may take longer than usual (up to 1 year) to become pregnant after its use. More than 80% of patients treated with progestins will experience partial or complete pain relief.[123] Although devoid of the menopause-like adverse effects of other medications used to treat endometriosis, DMPA is associated with weight gain (which may be significant in some patients), bloating, and irregular periods or bleeding for several months, with most users eventually experiencing amenorrhea. To reduce bone density loss, which is significant but less than with GnRH agonists, N.H. should be advised to ensure her daily intake by diet or supplementation of calcium is at least 1,000 mg/day and at least 400 to 600 IU of vitamin D/day, receive smoking cessation counseling and pharmacotherapy as appropriate, and start a regular weight-bearing exercise regimen.[135] She should be monitored for pain relief, weight gain, amenorrhea or bleeding changes, and adherence to the quarterly injections. When N.H. desires conception, significant planning is required and she may require a different therapy for her endometriosis because she regains fertility.

GONADOTROPIN-RELEASING HORMONE AGONISTS AND ADD-BACK THERAPY

CASE 50-4

QUESTION 1: M.F., a 24-year-old single woman with a history of moderate-to-severe endometriosis, has been treated with some benefit with NSAIDs (three different NSAIDs at appropriate doses), combined oral contraceptives, and the levonorgestrel IUS. She has no desire for conception and is looking for pain relief. She has also had two conservative laparoscopic surgical procedures, each of which was successful, with pain relief lasting 6 months to 1 year. She recently had her "last ever" (by her description) surgical procedure and is looking to extend the improvement she has seen previously after surgery. She does not mind injections, but has had trouble with adherence in the past. What options are available for the treatment of M.F.'s pain?

M.F. has tried numerous pharmacologic and surgical treatments (NSAIDs, combined oral contraception, and progestin-only contraception) for endometriosis with limited benefit. Given that she does not desire pregnancy at this time, GnRH analogs, aromatase inhibitors, and danazol are other options. Leuprolide, nafarelin, and goserelin are GnRH analogs (agonists) typically used for the treatment of endometriosis (Table 50-4). Although GnRH analogs have not been shown to produce better results than the therapies M.F. has already used, they may provide her with pain relief. Choice of GnRH agonist is driven by patient choice of administration method (nasal twice daily [BID] with nafarelin, monthly SC implant with goserelin, or IM injection either once monthly or once every 3 months with leuprolide). In M.F.'s case, the once every 3 months dosing with leuprolide would be most desirable for her, eliminating the need for daily administration. Efficacy is similar for all the GnRH agonists. Before use of these agents, pregnancy, undiagnosed vaginal bleeding, and breastfeeding should be ruled out. Because M.F. does not desire conception, and use of the GnRH agonists is contraindicated in pregnancy, she should be counseled regarding choices of nonhormonal contraceptive agents.

Onset of response to GnRH therapy depends on the phase in the menstrual cycle during which the agent is initiated. Administration beginning in the luteal phase causes decreased estrogen levels within 2 to 3 weeks, and amenorrhea within 4 to 5 weeks versus the 6 to 8 weeks if started in the follicular phase.[99]

Usual therapy duration is 6 months, although a small pilot study suggested long-term treatment (up to 10 years) with estrogen add-back therapy is without major adverse effects, with continued efficacy.[136] Add-back therapy is based on the concept of an estrogen threshold hypothesis, formulated by Barbieri,[112] which states that there is a critical amount of estrogen that exacerbates endometriosis, and below that level the presence of estrogen serves to decrease adverse effects but does not have an adverse effect on the disease itself. Add-back therapy should be initiated at the beginning of GnRH agonist therapy to try to reduce the occurrence of all hypoestrogenic adverse effects.[136]

Estrogen-containing OCs contain a dose of estrogen that is above the threshold, and they should not be used for add-back therapy. Doses

---

of estrogen equivalent to 0.625 mg of conjugated equine estrogen have been studied in combination with either medroxyprogesterone 2.5 mg daily, or norethindrone 5 mg daily. This dose of norethindrone alone, or a dose of 20 mg of medroxyprogesterone alone, has also demonstrated benefit.[106] To prevent bone loss, a regimen of a progestin plus a bisphosphonate has been studied with positive results.

No studies have demonstrated superior efficacy or safety of one regimen over another. Women using add-back therapy should consume in diet or supplement a total of 1,000 mg of calcium daily, and have vitamin D levels in the normal range.[111]

Therapy beyond 3 to 6 months requires the use of add-back therapy to reduce the risk of hypoestrogenic complications. Monitoring for efficacy includes monitoring for amenorrhea, decreases in pain and dyspareunia, and quality of life. After discontinuation of GnRH agonists, menses and ovarian function return to normal in 6 to 12 weeks, although benefits may be maintained for another 6 to 12 months.[99]

Adverse Effects

Adverse effects should be discussed in detail with M.F. because they differ significantly from the other therapies she has tried. Adverse effects are related to the induction of the pseudomenopausal state. Nearly all patients experience hot flashes; vaginal dryness and insomnia also are common. GnRH agonists do not affect SHBG or testosterone levels, so the androgenic side effects of danazol, including changes in lipid profiles, are not experienced with these agents.[99] Significant bone loss can occur, necessitating adequate calcium and vitamin D intake, and estrogen add-back therapy to decrease loss.

A reduction in bone density is a significant concern with GnRH agonists, even at 3 months after the onset of therapy, and is particularly concerning because these agents are being used in young women, many of whom have not reached their peak bone mass. Studies have demonstrated a loss of 3.2% in lumbar spine bone mineral density after 6 months and up to a 6.3% decrease after 12 months of GnRH agonist treatment.[137] It has also been reported that endometriosis itself is also a risk factor for decreased bone density, although a long-term study did not find any association between endometriosis and fracture risk during a 20-year follow-up period.[138] Interestingly, this same study did not find any association between fracture risk and GnRH agonist therapy, although a significant number of women in the study did take add-back therapy.

Monitoring for decreases in bone density should be accomplished via dual-energy X-ray absorptiometry scan every 24 months if GnRH therapy is continued. M.F. should also be counseled regarding adequate calcium and vitamin D intake, smoking cessation, and a regimen of weight-bearing exercise.

M.F should initiate the leuprolide 11.25 mg IM once every 3 months, with add-back therapy consisting of conjugated estrogens 0.625 mg daily with 2.5 mg medroxyprogesterone. A 6-month trial followed by an evaluation of symptom control is reasonable.

MANAGEMENT OF ENDOMETRIOSIS-RELATED INFERTILITY

CASE 50-5

QUESTION 1: K.L. is a 32-year-old woman with a history of stage II endometriosis. She currently is using a levonorgestrel IUS for both contraception and control of her pain, with positive results. She also takes ibuprofen 800 mg TID on a regular basis. She and her spouse would like to have a child. About 6 years ago, they attempted to conceive without success after 24 months. K.L is concerned that she will now have even more difficulty in becoming pregnant, given her advanced age. What are the recommendations for improving fertility in K.L?

Of women presenting to the healthcare system with infertility, 25% to 50% have endometriosis and 30% to 50% of women with endometriosis are infertile.[139] Proposed mechanisms contributing to infertility include adhesions that impair oocyte transport, changes in the peritoneum not compatible with fertility, changes in hormonal function, endocrine or ovulation dysfunction, and disorders of implantation (see Chapter XX, Infertility). No evidence suggests that hormonal therapy, including therapy with GnRH agonists, improves conception rates for women with stage I/II endometriosis, similar to K.L. On the other hand, surgical ablation or resection of visible endometriosis implants is beneficial in improving pregnancy rates in women with stage I/II endometriosis.

For K.L., removal of her IUS, followed by laparoscopic ablation or resection of visible implants, may improve her ability to conceive, barring other factors influencing fertility (e.g., PCOS, male factor infertility, tubal patency).[140] For patients with more advanced disease, or in those patients older than 35 years of age, a more aggressive treatment regimen is appropriate. Options include the use of agents to induce superovulation (clomiphene) and the use of in vitro fertilization techniques with embryo transfer (IVF-ET). In women with endometriosis, the success of IVF-ET is decreased by as much as 20% when compared with women without endometriosis.[99] For women contemplating IVF-ET, three prospective clinical trials have demonstrated a potential benefit in women with stage II–IV endometriosis who were treated for 3 to 6 months or more with GnRH agonists before IVF-ET.[114] The treated subjects had significantly higher pregnancy rates compared with women who did not use GnRH agonists before IVF-ET.[141]

For women who have not yet demonstrated an inability to conceive, a “wait and see” approach, with use of an NSAID for pain, emotional support, and reassurance, for 6 to 12 months is appropriate in women younger than 35 years of age.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual symptoms occur in up to 95% of reproductive-age women.[142] Approximately 30% to 40% of these women have more bothersome symptoms of premenstrual syndrome (PMS), and it is estimated that 3% to 8% meet the criteria for premenstrual dysphoric disorder (PMDD), a more severe variant of PMS.[142] More than 200 premenstrual symptoms have been described as occurring during the days before menstruation, including positive symptoms, such as increased energy, libido, and ability to relax, as well as negative symptoms including abdominal distension, fatigue, headaches, and crying spells.[143] It is not until the symptoms have a decidedly negative influence on the physical, psychological, or social function of a woman that PMS or PMDD exists.

Diagnosis

No specific physical findings or laboratory tests can be used to make a diagnosis of PMS. Several different organizations have attempted to provide diagnostic criteria for PMS and PMDD; their criteria are inconsistent and disparate. The International Society for Premenstrual Disorders (ISPMD) published a consensus statement in 2011 that defined core premenstrual disorders as typical, pure, or reference disorders associated with spontaneous ovulatory menstrual cycles and variant premenstrual disorders that are separate from core premenstrual disorders and exist where more complex features are present (e.g., symptoms result from underlying disorder or exogenous progestogen administration).[144] Core premenstrual features (somatic and psychological symptoms) must occur during all or part of the 2-week premenstrual phase and resolve during or shorting after menstruation. A symptom-free interval between the end of menstruation and the time of ovulation must occur. This cyclic pattern must also occur in most (typically two out of three) menstrual cycles. Lastly, the severity of symptoms must (1) affect normal daily functioning; (2) interfere with work, school performance, or interpersonal relationships; or (3) cause significant distress. Core premenstrual disorder is an umbrella term for PMS and PMDD.

Table 50-5

ACOG Diagnostic Criteria for Premenstrual Syndrome

Affective Symptoms	Somatic Symptoms
Depression	Breast tenderness
Angry outbursts	Abdominal bloating
Irritability	Headache
Anxiety	Swelling of extremities
Confusion	
Social withdrawal	

Notes: (1) Diagnosis made if at least one affective or one somatic symptom is reported in the three prior menstrual cycles during the 5 days before the onset of menses. (2) The symptoms must resolve within 4 days of onset of menses and do not recur until after day 12 of the cycle. (3) The symptoms must be present in at least two cycles during prospective recording. (4) The symptoms must adversely affect social or work-related activities.

ACOG, American College of Obstetricians and Gynecologists.

Source: American College of Obstetricians and Gynecologists. ACOG Practice Bulletin. Clinical management guidelines for obstetrician-gynecologists. Premenstrual syndrome. Number 15, April 2000. Obstet Gynecol. 2000;95(4); Mishell DR. Premenstrual disorders: epidemiology and disease burden. Am J Manag Care. 2005;11:S473.

The American College of Obstetricians and Gynecologists (ACOG) published a Practice Bulletin in 2000 that defined PMS diagnostic criteria using cyclic patterns of symptoms in women.[145] PMS can be diagnosed if at least one of the affective or one of the somatic symptoms listed in Table 50-5 is reported 5 days before the onset of menses in the three previous cycles. The symptoms must be prospectively recorded in at least two cycles, must cease within 4 days of onset of menses, and must not recur until after day 12 of the menstrual cycle. A key factor that separates PMS from "normal" premenstrual symptoms is that work or social activities are adversely affected in PMS. Other diagnoses that may explain premenstrual symptoms should be excluded, including psychological, thyroid, and gynecologic disorders.[146]

The American Psychiatric Association has developed criteria for PMDD.[147] The criteria for PMDD focus on the mood and mental health symptoms, leading to a higher level of dysfunction compared with PMS. These criteria require prospective documentation of physical and behavioral symptoms (using diaries) being present for most of the preceding year; five or more symptoms present during the week prior to menses, resolving within a few days after menses starts; and PMDD may be superimposed on other psychiatric disorders, provided it is not merely an exacerbation of those disorders. One or more of the following symptoms must be present: mood swings, sudden sadness, or increased sensitivity to rejection; anger, irritability; sense of hopelessness, depressed mood, or self-critical thoughts; and tension, anxiety, or feeling on edge. Additionally, one or more of the following symptoms must be present to reach a total of five symptoms overall: difficulty in concentrating; change in appetite, food cravings, or overeating; diminished interest in usual activities; easy fatigability or decreased energy; feeling overwhelmed or out of control; breast tenderness, bloating, weight gain, or joint/muscles aches; and sleeping too much or not sleeping enough. Symptoms must have been present in most menstrual cycles that occurred the previous year, and the symptoms must be associated with significant distress or interference with usual activities (e.g., work, school, social life).

Although criteria for PMS and PMDD are different, they share three essential characteristics: (a) symptoms must occur in the luteal phase and resolve within a few days of menstruation, (b) symptoms are documented for at least two menstrual cycles and are not better explained by other physical or psychological conditions, and (c) symptoms are sufficiently severe to disrupt normal activities.

The symptoms of PMS and PMDD experienced by women can vary widely. Risk factors for PMS include advancing age (older than 30 years) and genetic factors.[146] Symptoms, however, can begin in adolescents around age 14, or 2 years postmenarche, and persist until menopause.[148] Some studies suggest that women with mothers reporting PMS are more likely to develop PMS than those with unaffected mothers (70% vs. 37%, respectively).[149,150] One article found that traumatic events, such as physical threat, childhood sexual abuse, and severe accidents, increased the risk of developing PMDD.[151]

Pathophysiology

The wide range of symptoms exhibited in patients with PMS or PMDD can be explained by multiple possible mechanisms, probably a result of interactions between sex steroids and central neurotransmitters.[152] Alterations in neurotransmitters, primarily reductions in serotonin, triggered by normal hormonal fluctuations of the menstrual cycle appear to be the most probable factors for the development of PMS or PMDD. Other neurotransmitters, including endorphins and γ-aminobutyric acid (GABA), have also been implicated.[153,154] The levels of estrogen, progesterone, and testosterone are normal in women with PMS, but they may be more vulnerable to normal fluctuations.[154] These potential mechanisms provide a rational basis for the symptoms that appear in PMS and PMDD, but also support the therapeutic benefits of treatments that increase serotonin or GABA levels. Many treatments have limited and variable efficacy, which reinforces the argumentation that PMS or PMDD is a result of multiple factors. Furthermore, placebo responses in trials can be as high as 50% to 80%, which points to an important psychosomatic component and the consideration that PMS or PMDD has relevant biological, psychological, and social factors.[143,155]

CASE 50-6

QUESTION 1: C.P., a 27-year-old woman, presents complaining of significant mood changes that occur the week before her menstrual cycle. She experiences increased irritability and anxiety as well as breast tenderness and abdominal bloating. These symptoms usually subside the first or second day after her menses begin. For 2 to 3 weeks after her menstrual period, C.P. is her “normal, usual self” until the symptoms begin again just before her next menstruation. She has had these symptoms every month for the past several years. She states that she is very uncomfortable when these symptoms occur. Although she is able to work most of the time, she typically avoids going out with her friends when she has these symptoms. Her menstrual cycles are regular, occurring every 28 to 30 days with a light flow lasting 3 to 4 days.

Pelvic, cardiovascular, and neurologic examinations are normal, and all laboratory assessments are within normal limits. Her serum pregnancy test was negative. She is sexually active and uses condoms for contraception. She has no significant past medical history and she does not take any medications. What symptoms does C.P. have that are consistent with a diagnosis of PMS?

C.P. has symptoms that meet the ACOG criteria for PMS. Her affective symptoms include irritability and anxiety, and somatic symptoms include breast tenderness and abdominal bloating. These symptoms occur during the luteal phase of the menstrual cycle, resolve within 4 days of menses, and do not recur until after day 12 of her cycle. C.P.'s symptoms appear to be affecting her social activities. She states that these symptoms have been present for years and that they occur every month, although she has not prospectively recorded this information. C.P. does not meet the criteria for PMDD because her symptoms are not severe or markedly impairing her ability to participate in daily activities.

Treatment: Premenstrual Syndrome

CASE 50-6, QUESTION 2: C.P. asks about nonprescription therapy. Which agents, if any, are appropriate for C.P.?

The management of premenstrual disorders has been outlined by the ISPMD.[155] Treatment may be aimed at symptoms, especially if one particular symptom is dominant. Nonprescription options that have been studied and have demonstrated at least minimal benefit include calcium, magnesium, pyridoxine, chaste tree or chasteberry, and some mind–body approaches. Acetaminophen and NSAIDs may be beneficial for the physical symptoms of PMS, but diuretics found in various OTC products (e.g., ammonium chloride, caffeine, pamabrom) have limited data and unproven efficacy. Given the high placebo response rate in PMS, only agents with clinically proven efficacy should be used.

CALCIUM

Increased estrogen during the middle of a normal menstrual cycle decreases calcium. In women with PMS, intact parathyroid hormone (PTH) increases in response to this change compared with no PTH change in women without PMS.[156] Therefore, women with PMS have mid-cycle elevations of intact PTH with transient, secondary hyperparathyroidism that increases calcium demands. Calcium supplementation may help to normalize these processes and explains why calcium has demonstrated some benefit in women with PMS.

Three calcium trials have shown efficacy of PMS symptoms. A randomized, double-blind crossover trial of 33 women receiving 1,000 mg elemental calcium daily or placebo for 3 months reported a significant overall 50% reduction in PMS symptoms for women taking calcium compared with placebo.[157] In a double-blind study of 10 women assigned to dietary calcium intake, 1,336 mg daily was found to benefit mood, behavior, pain, and water retention symptoms significantly during the menstrual cycle.[158] Perhaps the most convincing evidence comes from a prospective, multicenter, randomized, double-blind, placebo-controlled, parallel-group trial conducted in 466 women with PMS.[159] Elemental calcium 1,200 mg daily (given as 600 mg BID) for three menstrual cycles significantly decreased negative affect, water retention, food cravings, and pain compared with placebo. Overall, the calcium-treated group had a 48% reduction in luteal symptoms compared with a 30%

reduction in the placebo group. Because calcium is well tolerated and may provide other benefits (e.g., osteoporosis prevention), calcium supplementation should be recommended to women with symptoms of PMS if inadequate through diet or other supplementation.

MAGNESIUM

Low levels of red cell magnesium have been correlated with women experiencing PMS; therefore, magnesium supplementation has been evaluated for PMS symptoms.[160] A Cochrane review of three small trials comparing magnesium and placebo in women with dysmenorrhea concluded that magnesium was more effective for pain associated with PMS and the need for additional medication was less for those taking magnesium.[89] Magnesium doses that have been studied for PMS vary from 200 to 360 mg orally daily. Trials have reported improvements in fluid retention and negative affect, but findings have not been consistent.[161] The most common side effects affect the gastrointestinal system (e.g., nausea, diarrhea). The conflicting results may be caused by differences in the dosing regimens of the magnesium and differing levels of magnesium stores in the study subjects. Available data support the use of magnesium in PMS, but more research is needed.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 has been noted to have positive effects on neurotransmitters, such as serotonin.[162] The most comprehensive information for this nutrient comes from a systematic review of nine trials representing 940 patients with PMS.[163] The overall assessment of the review was that women with PMS are likely to benefit from vitamin B_6 supplementation at a dose of 50 to 100 mg daily. An analysis of four of the trials, which specifically examined depressive symptoms, showed that pyridoxine was more effective than placebo in reducing depressive symptoms (OR, 1.69; 95% CI, 1.39–2.06). Although the conclusions of this review were positive, the authors felt there was insufficient evidence of high quality to recommend vitamin B_6 for PMS. Because neuropathy has been reported with pyridoxine dosages as low as 200 mg/day, patients should be advised to monitor for symptoms, discontinue therapy, and seek medical attention if they occur.[163]

CHASTETREE OR CHASTEBERRY

Chasteberry (Vitex agnus-castus or VAC) is the fruit of the chaste tree, a small shrub-like tree native to Central Asia and the Mediterranean region. Liquid or solid extracts from the dried ripe chasteberry are used to make chasteberry capsules and tablets. The mechanism of action of chasteberry relative to PMS is unclear, but several trials have reported its beneficial effects. In a study of 1,542 women with PMS taking chasteberry extract, 33% of subjects reported total relief of symptoms and an additional 57% reported partial relief after 4 months.[164] Of patients, 2% complained of adverse events including nausea, allergy, diarrhea, weight gain, heartburn, hypermenorrhea, and gastric complaints. A randomized, double-blind, placebo-controlled trial of 170 women taking chasteberry extract 20 mg daily for three menstrual cycles showed a treatment response rate of 52% compared with 24% for placebo ($p < 0.001$).[165] Individual symptoms of irritability, mood alteration, anger, headache, and breast fullness were reduced. Bloating was not significantly altered compared with placebo. The incidence of side effects was low, but long-term safety is unknown. A prospective, randomized, placebo-controlled study in 67 Chinese women showed that one VAC tablet daily containing 40 mg of herbal drug produced an 85% efficacy rate compared with a 56% efficacy rate for placebo on symptom scores after three treatment cycles.[166] In general, data indicate that chasteberry may be effective for PMS, but should probably not be used as routine treatment for PMS.[161]

MIND–BODY APPROACHES

Evidence regarding mind–body approaches for PMS is somewhat limited. Because these modalities are risk-free and they are generally accepted as components of a healthy lifestyle, they are favored in the treatment of PMS. Mind–body approaches that have demonstrated benefit in PMS include relaxation response, cognitive-behavioral therapy, yoga, aerobic exercise, and light therapy.[167] Trials that have evaluated acupuncture have demonstrated benefit to patients with PMS, but there are significant flaws in study designs that prevent it from being recommended as a treatment modality.[168]

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND DIURETICS

NSAIDs have been used to relieve the physical symptoms (e.g., headache, joint pain) of PMS, but do not improve the mood symptoms.[146] Regimens have included taking naproxen or mefenamic acid during the luteal phase and stopping therapy after menses begin. Diuretics commonly found in OTC products, such as ammonium chloride, caffeine, and pamabrom, are not effective.

Several OTC options are available to C.P. Trials including calcium, magnesium, pyridoxine, and chasteberry have shown some positive findings, but the evidence is not compelling due to methodological limitations. These treatments should not be recommended for the treatment of PMS, but may already be included in a healthy diet or vitamin regimen. Mind–body approaches, such as yoga and relaxation, are part of a healthy lifestyle and could be recommended to C.P. Because C.P. is having mood symptoms (i.e., anxiety), NSAIDs would not be an effective recommendation.

CASE 50-6, QUESTION 3: C.P. has been taking a multivitamin daily for 3 months with adequate amounts of calcium, magnesium, and vitamin B_6 for PMS relief. She also has been taking naproxen sodium 220 mg orally

BID without significant reduction of her symptoms. Her physician requests that she keeps a daily dairy for two consecutive cycles to document her symptoms. What information should be included in this tool?

C.P. should keep a daily diary for two consecutive menstrual cycles to demonstrate a temporal relationship between her symptoms during the luteal phase and to document the severity of these symptoms (Table 50-6). In addition, she should indicate the presence of menstrual flow, weight, and daily basal body temperature readings to help determine when ovulation occurs. The diary establishes a baseline for each patient and documents the most troublesome symptoms. Once therapy is selected for these symptoms, the diary can aid in assessing patient response.

Treatment: Premenstrual Dysphoric Disorder

CASE 50-6, QUESTION 4: C.P. returns to clinic with the diary presented in Table 50-6. The physician determines that C.P. actually has PMDD. What evidence supports this diagnosis and what should be recommended to C.P. for treatment?

C.P. meets the criteria for PMDD as evidenced by her symptoms during the 1 week before her menstrual cycle (luteal phase). Specifically, she has at least five symptoms required for the diagnosis of PMDD: sadness or depression (core symptom), fatigue, irritability, inability to concentrate, breast tenderness, and bloating. She rated several of those symptoms as severe, which indicates the symptoms are disabling and she is unable to meet her daily obligations. There is no reason to suspect any other disorder based on her history. PMDD seems to be the most likely diagnosis for C.P.

Therapy options at this time include lifestyle modifications, psychosocial interventions, and pharmacologic therapy. Psychotropic drugs targeted to her most severe symptoms may include selective serotonin reuptake inhibitors (SSRIs), serotonergic tricyclic antidepressants, and anxiolytics. Oral contraceptives have also been approved for PMDD and could be considered.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Serotonin is critical in the pathogenesis of PMDD, and for that reason, SSRIs have become the treatment of choice for PMDD and severe PMS (Table 50-7).[169] SSRIs have demonstrated efficacy in reducing irritability, depressed mood, dysphoria, psychosocial function, and the physical symptoms of PMDD, including bloating, breast tenderness, and appetite changes. Fluoxetine, sertraline, and paroxetine controlled release each have an approved indication for PMDD.

The onset of SSRI effect in women with PMDD or severe PMS is much more rapid than when these agents are used for treatment of major depression or anxiety disorders.[169] Women may experience symptom relief or resolution within the first days of treatment versus 4 to 8 weeks for other psychological disorders.[155] Several different dosing strategies have been studied, including continuous dosing (once daily), intermittent dosing (last 2 weeks of menstrual cycle or luteal phase), and semi-intermittent dosing (continuous administration throughout the cycle with increased doses during luteal phase).[169] Continuous dosing would be reasonable for women with concurrent mood or anxiety disorders or those who may have difficulty in remembering the timing of the intermittent dosing. Intermittent dosing should be considered for patients with regular menstrual cycles who are able to adhere to the regimen, an absence of symptoms during the follicular phase, concerns about long-term effects (e.g., sexual dysfunction) or cost of daily therapy, and few side effects at treatment initiation.[169] Studies evaluating these dosing strategies have reported equal efficacy for continuous or intermittent strategies; treatment should be individualized based on patient history, willingness to adhere to therapy, and drug response.[170]

In a systematic review of 31 randomized controlled trials including fluoxetine, paroxetine, sertraline, escitalopram, and citalopram, SSRIs reduced overall self-rated symptoms significantly more effectively than placebo (end scores for moderate dose SSRIs: SMD −0.65, 95% CI −0.46 to −0.84, nine studies, 1,276 women).[170] Withdrawals due to adverse effects were significantly more likely in the SSRI group (moderate dose: OR 2.55, 95% I 1.84–3.53, 15 studies, 2,447 women) with side effects being dose-dependent and most commonly reported as nausea (NNH = 7), asthenia or decreased energy (NNH = 9), somnolence (NNH = 13), fatigue (NNH = 14), decreased libido (NNH = 14), and sweating (NNH = 14). Overall quality of the evidence was considered to be low to moderate, with poor reporting of methods as the prominent weakness.

OTHER PSYCHOTROPIC AGENTS

Non-SSRI antidepressants that affect serotonin are also beneficial in treating PMS and PMDD (Table 50-7). Venlafaxine, dosed daily, is significantly better than placebo at relieving psychological and physical symptoms of PMDD.[171] Alprazolam is a short-acting benzodiazepine that has been assessed for the treatment of PMS in several studies with differing results.[172] With conflicting data and concerns about dependence, alprazolam should be reserved for women who are unresponsive to other PMS treatments. Luteal-phase dosing may limit the risk of drug dependence of this benzodiazepine, but the dose should be tapered during several days to minimize mild withdrawal symptoms. Buspirone, a partial 5-hydroxytryptamine receptor agonist, demonstrated significant reduction in irritability when given daily, but does not seem to affect the physical symptoms of PMS.[173]

COMBINATION ORAL CONTRACEPTIVES

Two low-dose combination oral contraceptive (COC) formulations containing 20 mcg ethinyl estradiol and 3 mg drospirenone (an antimineralocorticoid spironolactone analog) with a 4-day hormone-free interval have been approved for the treatment of emotional and physical symptoms of PMDD.[174,175] Studies using this agent have shown efficacy for reduced mood, physical, and behavioral symptoms of

PMDD, including a 48% improved response with this agent compared with a 36% response using placebo ($p = 0.015$).[176] Side effects occurring in at least 10% of women treated with this medication included intermenstrual bleeding, headache, nausea, breast pain, and upper respiratory infection. Another COC approved for PMDD contains 20 mcg of ethinyl estradiol, 3 mg of drospirenone, and 0.451 mg of levomefolate calcium.[176] In a systematic review of five randomized controlled trials comparing COCs containing drospirenone to placebo or other COCs for effect on premenstrual symptoms, the authors concluded that drospirenone 3 mg plus ethinyl estradiol 20 mcg may help treat PMDD better than placebo.[177] They were unable to determine whether this combination would help women with less severe symptoms or would be more effective than other COCs. For women desiring contraception, these particular agents have only been evaluated for efficacy in PMDD when used for up to three cycles. The effects of other contraceptive agents for PMDD symptoms are currently under investigation.

Table 50-6

Menstrual Cycle Daily Diary Chart

Month 1																
Grading Severity of Symptoms: 1 = Mild; general awareness of discomfort but does not interfere with daily activities 2 = Moderate; interferes with activities but not disabling 3 = Severe; symptoms disabling, unable to meet daily social, family, or work obligations * = Menstrual bleeding Blank = no symptoms																E 1 y 2 3 4 5

Nefazodone (Serzone)	200–600	NS
Venlafaxine (Effexor)	50	NS
Anxiolytics		
Alprazolam (Xanax)	NS	1–2[c]
Buspirone (BuSpar)	NS	25–60

[a] Day 14 until onset of menses.

[b] Medication has FDA-approved indication for premenstrual dysphoric disorder.

[c] Dose to be tapered during 2 days after onset of menses to prevent withdrawal symptoms.

NS, not studied; SSRI, selective serotonin reuptake inhibitors.

OTHER AGENTS

Treatment with GnRH agonists has been used for the physical and psychological symptoms of PMS.[178] These agents are not typically used for long periods of time, however, because of vasomotor symptoms and the potential for negative long-term effects on bone. They also have to be administered by injection or nasal spray which may affect adherence. This treatment is reserved for women with very severe PMDD who do not respond to other treatments.

Danazol has been investigated for the treatment of PMS with moderate results. Danazol 200 mg orally BID provides greater symptom relief than placebo for symptoms of severe PMS; however, luteal phase treatment does not appear effective for PMS symptoms.[179] Potential side effects are also a concern with this agent, and therefore, its use in women should be limited to those who have failed other therapies.

C.P. has PMDD and does not need contraception because she uses condoms. Mood symptoms predominate and are impairing her functionality. An SSRI should be started in either a continuous or intermittent manner. C.P. appears to be a good candidate for intermittent therapy because she can adhere to the regimen and does not have a concurrent depression or anxiety disorder. An appropriate initial treatment regimen is fluoxetine 20 mg orally daily for the last 2 weeks of the menstrual cycle. Her response rate should be assessed after three cycles of treatment. An anxiolytic could be tried for symptoms not relieved by the SSRI.

The Transition Through Menopause

Louise Parent-Stevens and Trisha LaPointe

CORE PRINCIPLES

		CHAPTER CASES
1	Menopause is the natural progression of reproductive aging in women. It is characterized by declining ovarian function and decreased synthesis of sex hormones.	**Case 51-1 (Question 1), Figure 51-1**
2	Management of women who experience distressing symptoms associated with menopause, including hot flushes and genitourinary atrophy, is targeted at relieving symptoms while minimizing risks.	**Case 51-1 (Questions 1–6), Case 51-2 (Questions 1–2), Figure 51-2**
3	Estrogen therapy (ET), the most effective treatment for menopausal symptoms, is associated with significant risks, including thromboembolic disease and breast and endometrial cancer. Progestogens are added to systemic estrogen therapy (EPT) to provide protection against endometrial hyperplasia and cancer in women with an intact uterus. Women must be adequately counseled so that they can make educated decisions about treatment.	**Case 51-1 (Questions 3, 5), Table 51-1**
4	Hormone therapy (HT), including ET and EPT, can be achieved through a wide variety of dosage formulations and dosing regimens. Based on the current understanding of the risks and benefits of systemic HT, use should be limited to the management of menopausal symptoms at the lowest effective dose for the shortest time possible.	**Case 51-1 (Questions 4, 5), Table 51-2 and 51-3**
5	The optimal time for the use of HT is controversial; some studies suggest decreased cardiovascular risk when HT is initiated soon after menopause, whereas other studies show an increased risk of breast cancer when HT is started shortly after menopause.	**Case 51-1 (Question 3)**
6	Nonhormonal drugs, including serotonergic antidepressants and antiepileptic drugs, are useful alternatives in women who are unable or unwilling to take HT. Although use of herbal medicines for menopausal symptoms is common, efficacy and safety data on these products are limited.	**Case 51-1 (Questions 2, 6), Case 51-2 (Question 2), Table 51-4**
7	As vaginal atrophy does not wane with time after menopause, long-term use of low-dose vaginal estrogen can be recommended.	**Case 51-2 (Questions 1, 2)**

INCIDENCE, PREVALENCE, AND EPIDEMIOLOGY

The perimenopausal or climacteric phase in the female aging process (i.e., the time between the reproductive and nonreproductive years) is distinguished by waning ovarian function and irregular menstrual cycles. Menopause, the last spontaneous episode of physiologic uterine bleeding, is usually identified retrospectively after 12 months of amenorrhea and typically occurs 4 to 5 years after the onset of the perimenopause. If needed, menopause can be confirmed by a follicle-stimulating hormone (FSH) level greater than 40 international units/mL. Postmenopause is characterized by significantly decreased hormone levels that may contribute to an increased risk of disease, including osteoporosis and cardiovascular disease (CVD).[1,2]

The average age of women at menopause has remained relatively constant at 51 years despite a significant increase in life expectancy.[3] Women today may spend one-third of their lives in the postmenopausal state. There are an estimated 40 million postmenopausal women in the United States who are at risk for menopause-related health issues.[3,4] Age at menopause appears to be determined primarily by genetics but may be decreased by low body weight and poor health status. Cigarette smoking decreases age at menopause by 1 to 2 years.[5] Higher socioeconomic status and prior oral contraceptive use may increase age at menopause.[5] Cytotoxic drugs and radiotherapy may induce ovarian failure, and bilateral oophorectomy results in surgically induced menopause. Onset of menopause before age 40 is termed premature ovarian failure.

PATHOPHYSIOLOGY

Perimenopause results from an age-related acceleration in oocyte (immature female egg) degeneration and resistance to gonadotropins. The aging follicles produce less inhibin, which triggers increased production of FSH (Fig. 51-1).[6] Despite this increase in FSH levels, the declining ovary is unable to consistently produce mature follicles, resulting in frequent anovulatory cycles during the years approaching menopause. However, spontaneous ovulation can still occur, and contraception should be used if pregnancy is not desired. When all ovarian follicles have been depleted, menopause occurs. This corresponds with a 10- to 20-fold increase in FSH levels and a threefold increase in luteinizing hormone levels, which peak 1 to 3 years after menopause.[7]

Postmenopausal estrogen production is approximately 10% of premenopausal levels.[7,8] After menopause, circulating estrogen is largely estrone, whereas the more potent estradiol is the primary estrogen during the reproductive years.[7] Unlike the reproductive years, estrogen levels postmenopausally do not vary in a cyclic pattern. The source of postmenopausal estrogen is androstenedione, an androgen converted to estrogen by an aromatase enzyme found predominantly in fat, liver, and skin. Enzyme levels increase with age and body weight, resulting in higher estrogen levels in women with greater body fat.[7,9] The source of progesterone after menopause is the adrenal gland, because the failed ovary no longer produces progesterone. Androgen production declines by approximately 50% with normal aging; however, after menopause, the androgen-to-estrogen ratio increases markedly owing to the greater drop in estrogen levels, often resulting in mild symptoms of androgenism, such as hirsutism.[10]

CLINICAL PRESENTATION

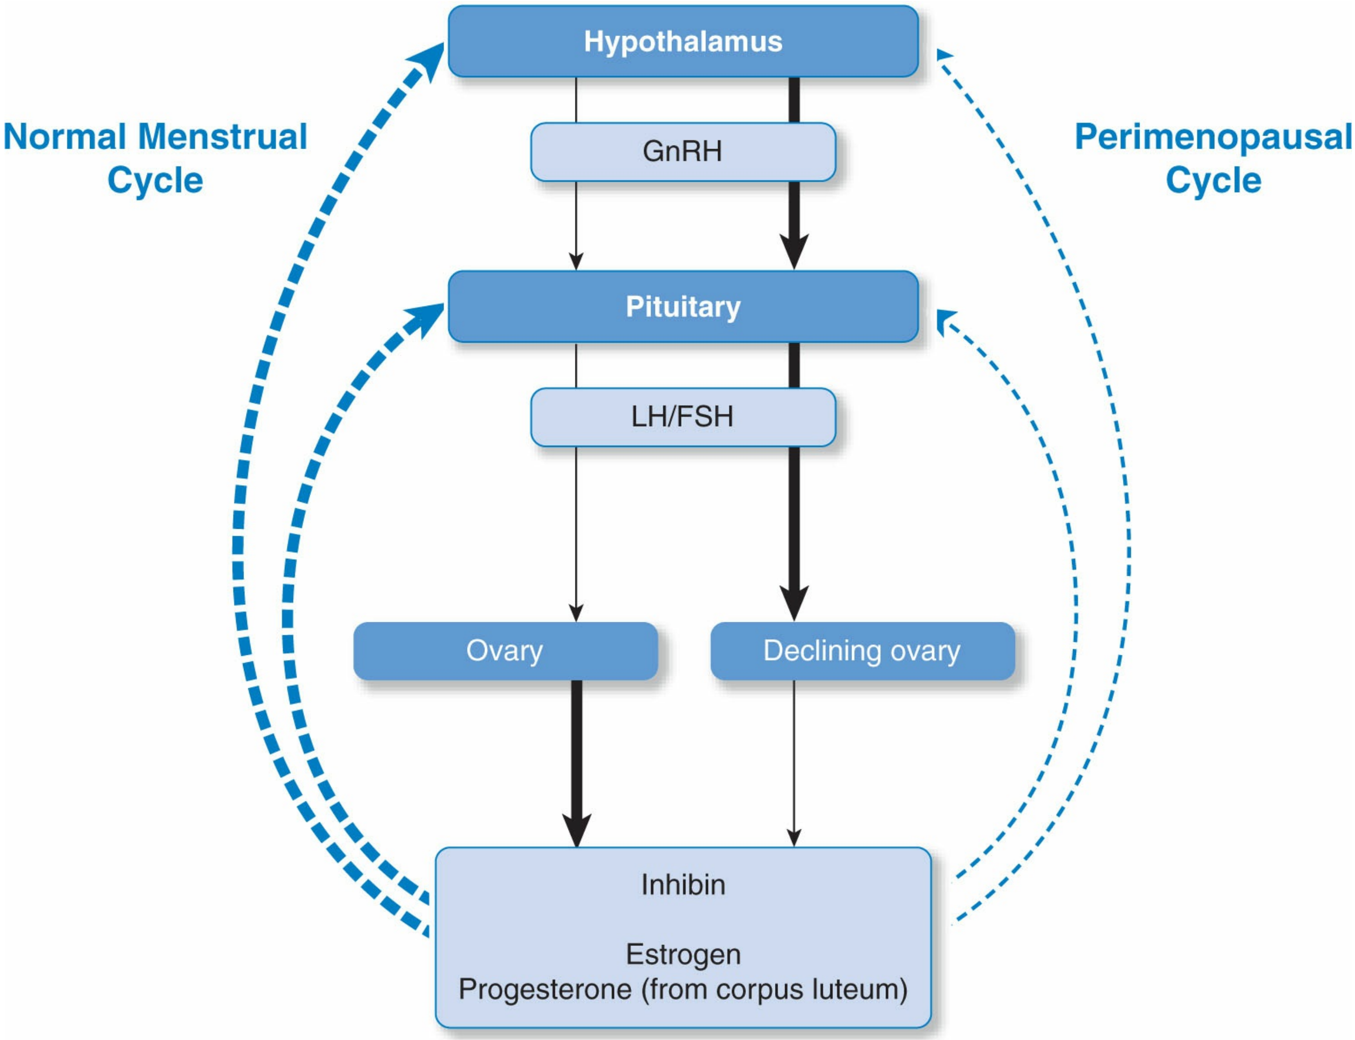
The decrease in estrogen production associated with menopause can result in clinical symptoms, such as hot flushes and genitourinary atrophy. The risk for CVD, the leading cause of death in postmenopausal women, appears to be amplified by estrogen deficiency.[1,2,5,11] Postmenopausal osteoporosis may result from estrogen deficiency (see Chapter 110, Osteoporosis). Loss of estrogen has also been associated with adverse effects on cognition, neurologic functioning, well-being, and sexual health.[2] Other consequences of menopause may not yet be elucidated.

Signs and Symptoms

HOT FLUSHES

CASE 51-1

QUESTION 1: L.K., a 50-year-old woman, is having sudden feelings of warmth over her chest accompanied by flushing of her skin and increased sweating for the past month, especially after drinking coffee or wine or if she is upset. These symptoms often wake her at night. She had a menstrual period 3 weeks ago, but recently her menses have been irregular (five menses in the past 12 months.) Her physical examination is normal for a 50-year-old woman. Her last mammogram 6 months ago was normal. She does not smoke, and her body mass index is 24 kg/m^2. She has hypertension that is controlled with hydrochlorothiazide 12.5 mg daily and migraine headaches without aura that she treats with sumatriptan 50 mg orally (PO) as needed. Her family history is positive for osteoporosis, but negative for CVD and breast cancer. Which of L.K.'s current symptoms are consistent with menopause?



Normal Menstrual Cycle
Perimenopausal Cycle
Hypothalamus
GnRH
Pituitary
LH/FSH
Ovary
Declining ovary
Inhibin
Estrogen
Progesterone (from corpus luteum)

Figure 51-1 Perimenopausal changes in hypothalamus–pituitary–ovary axis. Dashed line indicates inhibitory effect, Solid line indicates stimulatory effect and Wider line indicates more pronounced effect. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

It appears that L.K. is having hot flushes, a vasomotor symptom (VMS) experienced by 60% to 80% of women during the menopause transition.[12] The onset of VMS may precede the last menstrual period, but the prevalence peaks 1 year after menopause and declines with time since menopause.[13] Symptoms persist an average of 7 years; up to 30% of women may experience symptoms for longer than 10 years.[14] Obesity and surgically induced menopause are risk factors for more severe hot flushes.[15] Symptoms include a feeling of warmth in the chest, neck, and facial areas that may be accompanied by visible flushing and increased sweating. Nocturnal hot flushes (night sweats) cause nighttime awakening and may lead to insomnia and sleep deprivation. Hot flushes average approximately 4 minutes in duration and are characteristically episodic rather than continuous, but may occur hourly in women with severe symptoms.[10] Increased environmental temperature, ingestion of hot liquids or alcohol, and mental stress may provoke hot flushes.

The specific trigger for hot flushes is unknown, but they are clearly associated with the declining estrogen concentrations that occur during menopause. It is postulated that the drop in estrogen leads to a decrease in serotonin levels and an increase in the levels of norepinephrine and its metabolite, 3-methoxy-4-hydroxyphenylglycol. These hormones are involved in temperature regulation, and their fluctuations trigger an inappropriate activation of the body's heat-release mechanisms, leading to the cutaneous vasodilation and sweating seen with hot flushes.[10,16]

Cognitive and mood changes, including depression, are not uniformly associated with menopause, but are reported more frequently in women during the perimenopausal period.[17] Vaginal atrophy and urinary symptoms are also associated with menopause (see Case 51-2 Question 1).[10,18]

Overview of Therapy

Menopausal symptoms, while distressing, are not associated with increased mortality. Therefore, the goal of drug therapy in a symptomatic woman is to relieve symptoms and improve quality of life without increasing the risk of serious adverse outcomes related to the agents used.

TREATMENT

CASE 51-1, QUESTION 2: L.K. is seeking relief for her hot flushes but is not sure that she wants to use medications for this problem. What nonmedication therapies are appropriate for the management of L.K.'s hot flushes?

Lifestyle Modifications

First-line treatment for hot flushes is lifestyle modification, including avoidance of known triggers (e.g., hot beverages, alcohol, warm environments), wearing layered clothing, and use of personal cooling devices. Data on the efficacy of regular exercise, acupuncture, and relaxation techniques for VMS are limited.[19–21] If the patient continues to experience bothersome symptoms, drug therapy should be considered. It is noteworthy that placebo responses greater than 50% have been seen in clinical trials evaluating interventions for hot flushes.[22]

Black Cohosh

Black cohosh (Cimicifuga racemosa), an herbal product derived from a plant in the buttercup family, has a long tradition of use for the management of menopausal symptoms. It does not appear to have estrogenic effects, but may exert a serotonergic effect.[23] The efficacy of black cohosh for hot flushes is controversial; however, good results are reported in trials using a standardized extract containing 1 mg triterpene glycosides/20 mg tablet taken twice daily.[24] Black cohosh is generally well tolerated, but use beyond 12 months has not been evaluated. The most common adverse effects are gastrointestinal upset and rash. There have been case reports of hepatotoxicity which cannot be directly attributed to black cohosh.[23,24]

Phytoestrogens

Phytoestrogens, including isoflavones and lignans, are plant-based substances that exert mild estrogenic effects. Although epidemiologic studies show an association between higher dietary soy intake and fewer menopausal symptoms, meta-analyses of clinical trials of phytoestrogens concluded that they have minimal benefits on VMS.[22] However, several trials of the soy-derived isoflavone, genistein, reported significant improvement in VMS, which warrants further investigation.[22] In general, isoflavones are well tolerated; the most commonly reported side effect is gastrointestinal intolerance. Endometrial stimulation is rare but has been reported in a small number of patients after long-term use.[25,26] Because of their estrogenic effects, phytoestrogens should be avoided or used cautiously in women with a history of estrogen-dependent disease.

L.K. does not have any estrogen-dependent diseases and therefore could try either black cohosh or phytoestrogens for her hot flushes if lifestyle modifications do not provide adequate benefit. She should be counseled that these products have mixed data supporting their benefits and phytoestrogens could potentially have side effects similar to hormone therapy.

Hormone Therapy

CASE 51-1, QUESTION 3: L.K. returns to clinic after 2 months. She initiated lifestyle modifications and tried black cohosh but has noted worsening of her flushes, awakening multiple times nightly from night sweats, which is causing daytime fatigue and irritability. She asks about hormone therapy to control her hot flushes. Is L.K. a candidate for hormone therapy?

Hormone therapy (HT) has received a great deal of scientific and media attention during the past decade. The Women's Health Initiative (WHI), the only large, prospective study of estrogen therapy (ET) and estrogen/progestogen (EPT) therapy in postmenopausal women, and several large cohort studies have provided a great deal of data, some of it conflicting, on the risks and benefits of hormone use after menopause.[27–29] Before selecting a treatment option, women should be evaluated for contraindications to HT and counseled about its possible risks and benefits (Table 51-1).

Established Benefits of Hormone Therapy

Vasomotor Symptoms

Estrogen, with or without a progestogen, is well documented to reduce the frequency and severity of hot flushes. In women with hot flushes, HT has been shown to improve quality of life and depressive symptom.[27] During perimenopause, combination hormonal contraceptives are effective in reducing VMS as well as preventing pregnancy.

Osteoporosis

Estrogen, with or without a progestogen (ET/EPT), is proven to prevent bone loss associated with menopause, reducing the risk of osteoporotic hip and vertebral fractures by approximately 25%.[29] Many estrogen products are US Food and Drug Administration (FDA)-approved for the prevention (but not treatment) of osteoporosis (Table 51-2), and ET or EPT may be used for the prevention of osteoporosis in recently menopausal women, even in the absence of menopausal symptoms, if alternate osteoporosis therapies cannot be used.[27] Systemic ET maintains bone density, but bone loss resumes with estrogen discontinuation. Alternative therapies should be considered in women at risk for osteoporosis who stop ET or avoid its use altogether (see Chapter 110, Osteoporosis).[27,30]

Table 51-1

Risks and Benefits of Postmenopausal Hormone Therapy

	Evidence	Absolute or Relative Contraindications and Patient Considerations	References
Established Benefits[a]			
VMS	Systemic ET (in women without a uterus) or EPT (in women with a uterus) is most effective therapy for hot flushes. There may be a dose–response relationship. Oral and TD estrogens are equally effective.	This is the primary indication for the use of systemic hormone therapy.	45,79
Osteoporosis	Numerous clinical trials support reduced risk of vertebral and hip fractures with the use of estrogen.	Provides bone protection during use of ET/EPT for menopausal symptoms. May be used in recently menopausal women at risk for osteoporosis if other therapies are not feasible.	30,33,80
Vaginal atrophy	Numerous studies show both local and systemic estrogens reverse the atrophy induced by menopause.	Localized therapy should be used for patients with symptoms related solely to vaginal atrophy.	74,78
Established Risks[a]			

Thromboembolic disease	Increased risk of DVT and PE, greatest within the first year of use, risk with EPT possibly greater than with ET. TD estrogen has lower risk than oral estrogen.	**Absolute contraindication:** current tobacco use, history of thrombosis. **Relative contraindication:** obesity, women 65 years and older. Therapy should be discontinued before surgery or anticipated period of immobilization.	40–43,46
Breast cancer	Risk increased ˜25% after 5 years of use, increases with continued use. Greater risk with EPT and shorter exposure gap.	**Absolute contraindication:** personal history of breast cancer. **Relative contraindication:** strong family history of breast cancer.	27,36,37
Cardiovascular disease	Increased risk of MI, when started >10 years after menopause or in women ≥60 years old (see also unconfirmed benefit).	**Relative contraindication:** age 60 years or older, >10 years postmenopause.	27
Endometrial cancer	Risk related to dose and duration of use. Addition of adequate progestogen reduces or eliminates risk.	Rationale for the use of concomitant progestogen in women with uterus. **Absolute contraindication:** undiagnosed postmenopausal vaginal bleeding, prior history of endometrial cancer.	34
Ischemic stroke	30%–50% increased risk for **ischemic** stroke seen. Dose-related risk seen with both ET and EPT, may be less with nonoral route. Risk greater with increasing age (because of underlying age-related risk of stroke). HT does not affect risk of **hemorrhagic** stroke.	**Absolute contraindication:** history of stroke or transient ischemic attacks, current tobacco use. **Relative contraindication:** obesity, uncontrolled hypertension, uncontrolled diabetes.	33,81
Gallbladder disease	˜60% increased risk of cholecystitis, cholelithiasis seen with ET and EPT, less risk with nonoral route	**Relative contraindication:** history of gallbladder disease.	29,47
Hypertriglyceridemia	Oral estrogen increases triglycerides. Nonoral route has less effect. EPT may have less effect than ET alone owing to attenuating effect of progestogen.	**Relative contraindication:** hypertriglyceridemia. If estrogen is to be used in woman with elevated TG, select transdermal route and monitor TG levels.	27,82
Unconfirmed Benefits[b]			
Cardiovascular disease	No increased risk or possible decreased risk when initiated prior to age 60 and within 10	Prevention of CVD is not a primary indication for use; this information can reassure	31,32

	years of menopause (see also established risk).	patient needing HT for menopause symptoms or replacement for women with premature ovarian failure.	
Colorectal cancer	Decreased risk is seen with EPT but not with ET.	May be secondary benefit in women using for hot flushes.	83

Recurrent UTIs	Low-dose localized estrogen treatment can decrease risk for recurrent UTIs.	May be secondary benefit in women using localized therapy for vaginal atrophy.	84
Diabetes mellitus	Decreased incidence of new-onset diabetes in women taking EPT or ET.	This suggests that DM is not a contraindication for women who wish to use EPT/ET.	27
Unconfirmed Risks[b]			
Ovarian cancer	Increased risk seen with ET/EPT, longer durations of treatment	**Relative contraindication:** strong family history of ovarian cancer.	85
Lung cancer	Reports of protective effect but in WHI increased mortality from lung cancer seen in older current/past smokers.	**Absolute contraindication:** current tobacco use (owing to increased risk of TED).	27,28
Urinary incontinence	Systemic estrogen caused or worsened urinary incontinence, not seen with ultralow dose	Avoid systemic estrogen in women with urinary incontinence, monitor for new onset in women taking HT.	48,86
Cognitive effects	Studies report worsening of dementia in women with preexisting dementia; no improvement or protection in older women taking HT.	**Absolute contraindication:** patients with evidence of dementia. Avoid use in women ≥65 years.	87
Migraine headaches	HT may cause worsening of migraine headaches.	**Absolute contraindication:** migraine with aura (increased risk of stroke). **Relative contraindication:** migraine without aura—monitor for changes in HA frequency.	88

[a] Well-documented risk or benefit supported by multiple clinical studies.

[b] Possible risk or benefit shown in limited clinical trials, additional data needed to confirm.

CVD, cardiovascular disease; DM, diabetes mellitus; DVT, deep venous thrombosis; EPT, estrogen and progestogen therapy; ET, estrogen therapy; HA, headache; HT, hormone therapy; MI, myocardial infarction; PE, pulmonary embolism; TD, transdermally; TED, thromboembolic disease; TG, triglycerides; UTI, urinary tract infection; WHI, women’s health initiative.

Cardiovascular Disease

The cardiovascular effects of HT are not fully elucidated. Analysis of data from the WHI and other studies found no increased risk of coronary heart disease in women aged 50 to 59 years who began therapy within 10 years of menopause, and a possible reduced risk in women initiating therapy prior to age 55 and within 2 to 3 years of menopause, whereas an increased risk of CVD was seen in women aged 60 years and older who initiated HT more than 10 years after menopause.[31,32] In younger patients such as L.K. who initiate HT for VMS soon after the onset of menopause, the risk of CVD is not significantly increased.

Other Possible Benefits

Other less established benefits of HT (Table 51-1) include effects on urinary tract infections, diabetes mellitus, and colorectal cancer.[33]

Established Risks of Hormone Therapy

Cardiovascular Disease

As noted above, an increased risk of CVD has been noted in women over the age of 60 years who initiated HT more than 10 years postmenopause.[31,32]

Endometrial Cancer

Endometrial proliferation from exogenous estrogen exposure leads to hyperplasia rates of 8% to 62% after 1 to 3 years of use.[34] In a woman with a uterus, use of ET alone increases the risk of endometrial cancer by twofold to 10-fold, with higher estrogen dose and longer duration associated with greater risk.[27] The risk persists for several years after discontinuation of ET.[27] Addition of adequate progestogen significantly attenuates or eliminates the increased risk of endometrial cancer; a progestogen should be added to ET in a woman with an intact uterus (see Case 51-1, Question 4).[27,34]

Breast Cancer

Studies demonstrate a 25% overall increased risk of invasive breast cancer with EPT use, becoming significant 5 years after initiation, increasing with continued use, and returning to baseline approximately 5 years after EPT is stopped.[27,33,35] ET increases this risk less than EPT.[36,37] Risk appears to be similar between oral and transdermal therapies, and no dose–response relationship has been established. Risk may be lower in overweight/obese women.[36] A short time frame between the onset of menopause and initiation of HT appears to significantly increase the risk for breast cancer compared with a longer interval.[27,33,38]

Thromboembolic Disease

HT use increases the overall risk for venous thromboembolic disease (TED), including deep venous thrombosis and pulmonary embolism, twofold.[27] This risk may be mediated by inhibition of hepatic synthesis of anticoagulant factors, including antithrombin, protein S, and protein C.[39] Transdermal estrogen appears to have a significantly lower risk than oral estrogen as it avoids the first-pass metabolic effects of oral therapy.[33,40,41] Observational data suggest that synthetic progesterone derivatives but not bio-identical progesterone further increases risk of TED.[41,42] Women who are older, have a higher body mass index, or have a prothrombotic mutation are at additional increased risk.[43] The risk is greatest within the first year of treatment and decreases upon discontinuation of HT. HT should be avoided in women with a history of or at high risk for TED.[27,43]

Table 51-2

Agents Labeled for Use in ET and EPT

Drug (Brand Name)	Route, Initial Dosage
Estrogens, Systemic[b]	
Conjugated equine estrogens (Premarin)[a]	PO 0.3 mg
Synthetic conjugated estrogens (Enjuvia)	PO 0.3 mg
Estropipate (piperazine estrone sulfate) (Ortho-Est)[a,c]	PO 0.75 mg
Micronized estradiol (Estrace)[a,c]	PO 0.5 mg
Estradiol transdermal system (various brand name products)[a]	TD 0.014 (ultralow dose)–0.025 mg/24-hour patch applied weekly or twice weekly
Esterified estrogen (Menest)[a]	PO 0.3 mg
Estradiol acetate tablet (Femtrace)[c]	PO 0.45 mg
Estradiol acetate vaginal ring (Femring)[c]	HDV 0.05 mg/24 hour ring inserted vaginally every 90 days
Estradiol topical emulsion/gel/solution (Divigel, Elestrin, Estrogel, Estrasorb, Evamist)[c]	TD 0.0125 mg to 0.75 mg (product dependent)
Progestogens (Minimum Recommended Dose to Prevent Endometrial Hyperplasia)[34]	
Medroxyprogesterone acetate (Provera generic and combo products)	PO 5 mg for sequential regimens; 2.5 mg for continuous regimens
Norethindrone acetate (Aygestin generic and combo products)	PO 2.5 mg for sequential regimens; 1 mg for continuous regimens
Micronized progesterone (Prometrium)[c]	PO 200 mg for sequential regimens; 100 mg for continuous regimens
Progesterone vaginal gel (Prochieve, Crinone)[c] Progesterone vaginal suppository (First Progesterone VGS)	V one full applicator of 4% gel every other day V 200 mg/day for 12 days

Levonorgestrel-releasing IUD (Mirena)	IU 0.02 mg/day
Examples of Estrogen and Progestogen Combination Products	
Prempro[a]	PO 0.3 mg CEE and 1.5 mg MPA
Premphase[a]	PO 0.625 mg CEE for 28 days with 5 mg MPA for last 14 days
Climara Pro[a,c] (estrogen)	TD 0.045 mg estradiol/0.015 mg levonorgestrel/24-hour patch once weekly
Low-dose Vaginal Estrogens (Localized Effect Only)	
Conjugated equine estrogen cream (Premarin)	LDV initial: 0.5–2 g cream (0.3125–1.25 mg CEE) daily
	Maintenance: 0.5–2 g cream (0.3125–1.25 mg CEE) once/twice weekly based on severity
Estradiol cream (Estrace)[c]	LDV initial: 2–4 g cream (0.2–0.4 mg estradiol) daily
	Maintenance: 1 g cream (0.1 mg estradiol) twice weekly
Estradiol ring (Estring)[c]	LDV 2-mg ring (0.0075 mg/day) every 90 days
Estradiol hemihydrate tablets (Vagifem and Vagifem LD)	LDV one tablet (0.01 mg) daily for 2 weeks, then one tablet twice weekly

[a] Approved by the US Food and Drug Administration for prevention of osteoporosis.

[b] Requires addition of progestogen in women with a uterus.

[c] FDA-approved bio-identical hormone.

CEE, conjugated equine estrogens; HDV, high-dose vaginal estrogen, sufficient absorption to produce systemic estrogenic effect (i.e., for treatment of hot flushes); IU, intrauterine; IUD, intrauterine device; LDV, low-dose vaginal estrogen, provides localized estrogenic effect (i.e., for vaginal atrophy), owing to low-dose, minimal systemic absorption; MPA, medroxyprogesterone acetate; PO, orally; TD, transdermally; V, vaginal.

Other Possible Risks

Other risks with HT include potential adverse effects on cognition and urinary tract function, an increased risk of stroke and the development of ovarian and lung cancer and gallbladder disease[33] (Table 51-1).

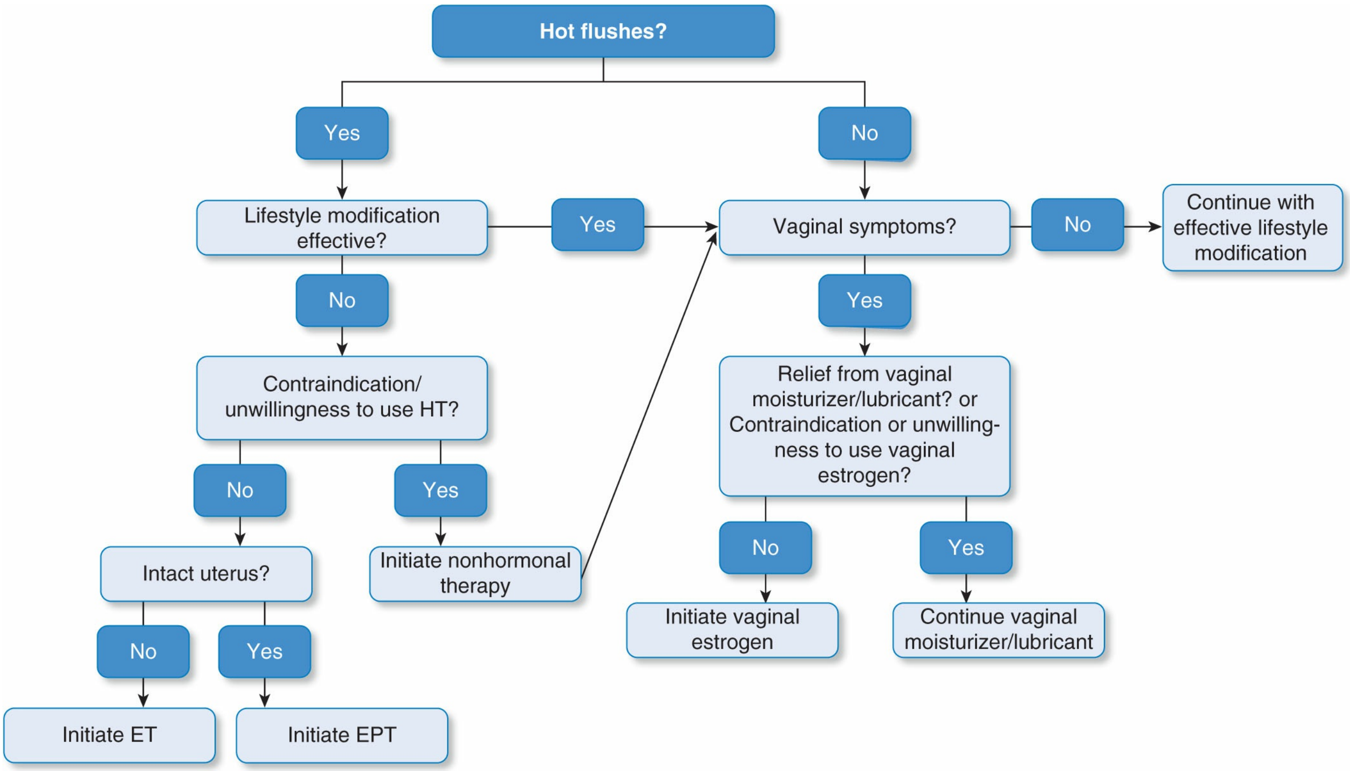
Recommendations

Current guidelines on systemic HT recommend its use only in women with moderate-to-severe hot flushes (Fig. 51-2).[27] For women with premature ovarian failure, it is recommended that HT be given until the typical age of natural menopause to avoid early manifestations of estrogen deficiency.[28,44]

As L.K. continues to experience severe hot flushes that are affecting her quality of life, she is recently postmenopausal, and she has no absolute contraindications to estrogen (such as TED, history of breast or endometrial cancer, uncontrolled hypertension, migraine with aura, tobacco use, obesity), a trial of HT is appropriate.

SELECTION OF THERAPY

CASE 51-1, QUESTION 4: What is an appropriate HT regimen for the management of L.K.'s hot flushes?



Hot flushes?
Yes
No
Lifestyle modification effective?
Yes
Vaginal symptoms?
No
Continue with effective lifestyle modification
No
Yes
Contraindication/ unwillingness to use HT?
Relief from vaginal moisturizer/lubricant? or Contraindication or unwillingness to use vaginal estrogen?
No
Yes
Intact uterus?
Initiate nonhormonal therapy
No
Yes
Initiate vaginal estrogen
Continue vaginal moisturizer/lubricant
No
Yes
Initiate ET
Initiate EPT

Figure 51-2 Algorithm for the management of symptomatic menopausal women. EPT, estrogen/progestogen therapy; ET, estrogen therapy; HT, hormone therapy.

Estrogens

There are a number of hormonal products currently available for the management of VMS (Table 51-2). Oral and nonoral estrogens appear to be equally efficacious in treating VMS.[27,45] Because it avoids first-pass metabolism, nonoral estrogen is associated with a lower risk for TED, hypertension, and gallbladder disease than oral ET.[42,46,47]

Current recommendations are to initiate estrogen at a low dose (e.g., 0.3 mg of conjugated equine estrogens or 0.025 mg of transdermal estradiol). Ultralow-dose estrogen (TD estradiol 0.014 mg/day) reduces the risk of harm but may not adequately control menopausal symptoms.[48,49] If symptoms persist after 2 to 3 weeks of therapy, the dose of estrogen can be increased to the next available dosage strength for the product being used (Table 51-2).[27]

Bio-identical Hormones

There is strong consumer interest in natural (bio-identical) HT (BHT) as a potentially safer alternative to synthetic estrogens. BHTs are defined as having the same chemical structure as the hormones produced by the human reproductive system and include estradiol, estrone, progesterone, and testosterone. Studies of commercially available BHT products demonstrate a similar efficacy to synthetic hormones; however, clinical evidence to support claims of greater safety is lacking.[50,51] Women desiring to use bio-identical products should be advised of commercially available products (Table 51-2); extemporaneously compounded BHT does not carry FDA-approved warnings and may be of inadequate quality.[51,52]

Progestogens

In women with an intact uterus, such as L.K., a progestogen must be added to the regimen to minimize the risk of endometrial cancer (Table 51-3).[27] Currently, there is no indication for adding a progestogen to ET in women without a uterus. There does not appear to be a difference in the endometrial protective effect between progestogens. Combined continuous regimens may provide better endometrial protection than sequential regimens (Table 51-3). Although not FDA-approved for this indication, progesterone vaginal gel and progestogen-releasing intrauterine systems protect against endometrial hyperplasia from ET.[53–55]

EPT may result in resumption of uterine withdrawal bleeding. The pattern and frequency of bleeding depend on the EPT regimen used (Table 51-3).[56] Lower doses of estrogen are associated with a lower risk of bleeding.[57,58] Patient preference regarding bleeding patterns should be considered when selecting an EPT regimen.

Progestogen monotherapy appears to be similar to estrogen in relieving the symptoms of VMS. Effective regimens include megestrol acetate, 40 mg/day orally, micronized progesterone 300 mg/day orally, and medroxyprogesterone acetate, 10 mg/day orally, 150 mg intramuscularly every 3 months or 400 mg intramuscularly one time.[59–62] Adverse effects of progestogens include vaginal bleeding, fluid retention, increased appetite, breast tenderness, acne, hirsutism, headaches, mood swings, fatigue, and depression. In the absence of ET, progestogens do not appear to increase the risk of TED.[61] However, data on long-term safety, especially in regard to breast cancer, are lacking. Progestogen monotherapy for the treatment of hot flushes is generally reserved for women with contraindications to estrogen use.

DURATION OF HORMONE THERAPY

As some risks of HT increase with longer use, use beyond 5 years has generally not been recommended. However, as many women continue to have VMS beyond this time frame, a thorough risk versus benefit review is needed to determine the appropriate duration for each woman.[63] Because hot flushes are self-limiting, it can be difficult to assess whether symptom relief is related to the treatment or natural resolution of symptoms. Six to 12 months after L.K.'s hot flushes are fully treated, she should attempt discontinuation of EPT. There are no specific guidelines for withdrawing therapy; typical taper regimens involve decreasing the daily estrogen dose to the next available dosage strength or increasing the dosing interval. If symptoms recur during the taper, therapy can be resumed at the lowest effective dose and another taper attempted in 6 months.[64–66]

Table 51-3

ET/EPT Regimens and Expected Vaginal Bleeding Patterns[56,89,90]

Estrogen/Progestogen Dosing	Hormone-Free Interval	Typical Bleeding Pattern
Combined Regimens (EPT) for Patient with Intact Uterus		
Intermittent Sequential		
Estrogen (PO or TD): days 1–25 of each month Progestogen: days 10–25 or 14–25 of each month	3–6 days	Withdrawal bleeding[c] 1–2 days after progestogen dosing ended[a]
		~80% experience regular bleeding
Combined Sequential		
Estrogen (PO or TD) and progestogen: days 1–25 of each month	3–6 days	Withdrawal bleeding[c] 1–2 days after progestogen dosing ended[a] Lower incidence than cyclic regimen
Continuous Sequential		
Estrogen (PO or TD): daily Progestogen: 10–14 days every month	None	Withdrawal bleeding[c] 1–2 days after progestogen dosing ended[a] ~80% experience regular bleeding
Long-cycle Sequential		
Estrogen (PO or TD): daily Progestogen: 14 days every third month	None	Withdrawal bleeding[c] 1–2 days after progestogen dosing ended[a] ~70% experience regular bleeding
Continuous Combined		
Estrogen (PO or TD) and progestogen: daily	None	~40% have irregular bleeding for first 6–12 months[b] ~75%–89% become amenorrheic within 12 months
Continuous Pulsed		
Estrogen PO × 3 days then Estrogen + Progestogen PO × 3 days Repeat continuously	None	~70% experience spotting[d] early during treatment ~80% are amenorrheic at the end of 12 months[b]
Estrogen-only Regimens (ET) for Patients Without Uterus		
Continuous Regimen		
Estrogen (PO or TD): daily	None	None

[a]Bleeding earlier than 11 days after beginning of the progestogen suggests need for endometrial evaluation.

[b]Bleeding more than 1 year after initiation of therapy requires endometrial evaluation.

[c]Withdrawal bleeding is vaginal bleeding for multiple days (usually <10 days) that resembles menstrual period and requires use of a tampon or sanitary pad.

[d]Spotting is light bleeding that lasts <1 day.

EPT, estrogen and progestogen therapy; ET, estrogen therapy; PO, orally; TD, transdermally.

ADVERSE EFFECTS

CASE 51-1, QUESTION 5: To minimize the risks of TED, L.K. is prescribed a combination estrogen/progestogen patch. How should she be counseled about possible side effects of EPT?

In addition to being counseled about the serious risks of EPT, L.K. should be advised regarding nuisance side effects from HT. These most commonly include resumption of vaginal bleeding and breast tenderness.[27,56] Nausea, weight gain, edema, headache, premenstrual syndrome-like symptoms, and increased vaginal discharge have also been reported. Skin irritation may occur with the use of transdermal products. Frequently, these side effects diminish with time or may respond to a change in dosage or product. Although ET and EPT have not been shown to consistently induce or worsen hypertension, patients with hypertension, such as L.K., should be monitored for increases in blood pressure.[67]

TISSUE-SELECTIVE ESTROGEN COMPLEX

The tissue-selective estrogen complex (TSEC) of conjugated estrogen (CE) and the selective estrogen receptor modulator (SERM), bazedoxifene (BZA), is FDA-approved for the treatment of VMS and the prevention of osteoporosis in postmenopausal women with a uterus. The CE component of this agent reduces VMS and prevents bone loss whereas the estrogen-antagonistic properties of BZA in the breast and uterus mitigate the effects of estrogen on these tissues, eliminating the need for concurrent progestogen.[68] Although not approved for this indication, studies suggest that CE/BZA improves symptoms of vaginal atrophy.[69] Clinical trials have demonstrated that CE/BZA produces fewer bleeding events and breast symptoms than the traditional combination of CE/MPA.[68] This agent is an alternative for women with a uterus who are unable or unwilling to use EPT due to adverse effects.

NONHORMONAL AGENTS

CASE 51-1, QUESTION 6: L.K. returns 3 months later. Her hot flushes and night sweats resolved with EPT, but she experienced worsening of her migraine headaches, so she discontinued HT. Her hot flushes recurred soon thereafter. What alternative therapies are available for the management of L.K.'s symptoms?

Table 51-4

Nonhormonal Agents for the Management of Vasomotor Symptoms[70–73,91]

Drug	Recommended Dosage	Adverse Reactions Reported
Serotonergic Antidepressants		
Citalopram (Celexa)	10–30 mg	Dry mouth, ↓ libido, rash/hives, insomnia, somnolence, bladder spasm, palpitations, arthralgias
Desvenlafaxine (Pristiq)	50–100 mg	Asthenia, chills, anorexia, nausea, vomiting, constipation, diarrhea, dizziness, nervousness, mydriasis, dry mouth
Escitalopram (Lexapro)	10–20 mg	Dizziness, lightheadedness, nausea, vivid dreams, increased sweating
Fluoxetine (Prozac)	10–20 mg	Nausea, dry mouth
Paroxetine hydrochloride (Paxil, Paxil CR)	10–20 mg 12.5–25 mg (CR)	Headache, nausea, insomnia, drowsiness
Paroxetine mesylate[a] (Brisdelle)	7.5 mg	
Sertraline (Zoloft)	50 mg	Nausea, fatigue/malaise, diarrhea, anxiety/nervousness
Venlafaxine (Effexor, Effexor XR)	37.5–75 mg 37.5–150 mg XR	Dry mouth, ↓ appetite, nausea, constipation, possible increase in blood pressure at higher doses
Antiseizure Agents		
Gabapentin (Neurontin)	900 mg, possibly up to 2,400 mg	Somnolence, fatigue, dizziness, rash, palpitations, peripheral edema
Pregabalin (Lyrica)	150–300 mg	Dizziness, sleepiness, weight gain, cognitive difficulty
Antihypertensive Agents		
Clonidine	PO: 0.05–0.15 mg TD: 0.1 mg/24 hour	Headache, dry mouth, drowsiness Skin reaction/itching (patch only), risk of rebound HTN if stopped abruptly

[a] FDA-approved for the management of vasomotor symptoms.

HTN, hypertension; PO, orally; TD, transdermally.

Nonhormonal agents, including serotonergic antidepressants and antiepileptic agents, are modestly effective in reducing hot flush frequency and severity. (Table 51-4) Decreased estrogen levels are thought to regulate endorphin concentrations in the hypothalamus thereby affecting serotonin and norepinephrine levels in the thermoregulatory area of the hypothalamus.[70] In clinical trials of serotonergic antidepressants, relief of vasomotor symptoms was seen at lower doses and with a more rapid onset than is seen for their antidepressant effects.[71,72] Venlafaxine and paroxetine, the most studied agents, are considered the drugs of choice; other selective serotonin reuptake inhibitors and serotonin and norepinephrine reuptake inhibitors are considered second-line agents.[72] Low-dose paroxetine mesylate is FDA-approved for the treatment of vasomotor symptoms; the dose of 7.5 mg is lower than that required for the treatment of psychiatric disorders.[70] Studies have shown that paroxetine mesylate is effective in decreasing the severity and frequency of vasomotor symptoms. Dosing should be initiated at the lowest effective dose (Table 51-4); this can be increased after 2 to 3 weeks if the patient has an inadequate response. Patients should be advised not to discontinue therapy abruptly to avoid withdrawal symptoms. Commonly seen side effects of nonhormonal agents are listed in Table 51-4. Of particular concern in postmenopausal women is the risk for anorgasmia and loss of libido; similar sexual dysfunction may also occur as a result of menopause. Patients should be advised to discuss the problem with their care provider if it occurs and is bothersome. The antiepileptic drug gabapentin has been shown in multiple studies to decrease hot flushes through an unidentified mechanism. The therapeutic effect occurs at a dose of 900 mg/day with an onset within 4 weeks of initiation of treatment. To minimize side effects, dosing should be initiated at 300 mg daily and titrated up in 300-mg/day increments as tolerated. Although one study showed benefit with 2,400 mg/day, the optimal dose of gabapentin for hot flushes is unknown.[71,73]

Paroxetine mesylate 7.5 mg daily can be tried in L.K. If her symptoms are not improved after 2 to 3 weeks, the dose can be titrated up to a maximum dose of 25 mg daily.

Genitourinary Atrophy

SIGNS AND SYMPTOMS

CASE 51-2

QUESTION 1: B.L., a 57-year-old woman, presents with a complaint of persistent vaginal dryness and irritation as well as pain associated with intercourse. She has tried vaginal lubricants, which help with intercourse-related pain but do not relieve her daily vaginal symptoms. She experienced menopause at age 50, which was accompanied by moderate hot flushes for 2 to 3 years that have since resolved without intervention. She denies symptoms of urinary incontinence. She does not smoke. On physical examination, her labia minora have a pale, dry appearance, and the labia majora appear flattened. Her vagina is small with a pale, dry epithelium. What is causing B.L.'s condition?

B.L. appears to be experiencing symptoms associated with genitourinary atrophy. Estrogen is the dominant hormone of vaginal physiology. With the postmenopausal loss of estrogen production, the vagina decreases in size and loses its rugal pattern. The mucosa becomes pale, thin, and dry, and vaginal blood flow decreases. A decrease in Lactobacillus production of lactic acid leads to an increase in vaginal pH to 5.0 or greater (compared with a premenopausal pH of 3.5–4.5).[18,74,75] These changes make the vagina more susceptible to infection from bacterial colonization and localized trauma secondary to intercourse. Unlike hot flushes, vaginal atrophy does not abate with time since menopause.

Symptoms of atrophic vaginitis include dryness, itching, pain, and dyspareunia (painful coitus). About 10% to 40% of postmenopausal women experience symptoms; however, only 7% of patients report these symptoms to their provider.[74] Postmenopausal women who engage in regular coital activity have less atrophic vaginal changes compared with those of similar age and estrogen levels who do not have regular intercourse.

TREATMENT

CASE 51-2, QUESTION 2: What would be an appropriate regimen for B.L. to decrease her vaginal symptoms?

Nonhormonal Treatment

First-line treatment includes vaginal moisturizers (e.g., Replens), which adhere to the vaginal mucosa, can improve vaginal symptoms but do not reverse atrophy.[75,76] Personal lubricants (e.g., KY jelly or liquid) can be used for women experiencing dyspareunia related to vaginal atrophy. Patients report symptom relief within 3 months of continuous treatment. Nonhormonal treatments used for vasomotor symptoms do not improve vaginal atrophy symptoms.[18,74,75]

Ospemifene (Osphena) is a vaginal tissue-specific estrogen agonist/antagonist. Ospemifene 60 mg once a day has demonstrated significant improvement in dyspareunia and vaginal atrophy. Duration should be restricted to the shortest amount of time possible based on patient's goals. Although ospemifene does not contain estrogen, it does have estrogen agonist effects and postmenopausal women with an intact uterus should be placed on progestin therapy as well. Serious adverse effects include increased risk of endometrial cancer and cardiovascular disorders.[77]

Localized Estrogen Treatment

Estrogen therapy reverses vaginal epithelial thinning, decreases the vaginal pH, and improves the symptoms of vaginal atrophy. Vaginal estrogen therapy has been shown to be more effective than systemic oral estrogen therapy, resulting in 80% to 90% response of vaginal atrophy.[74] For vaginal symptoms alone, low-dose vaginal estrogen is the preferred treatment.[74] The available products (Table 51-2) appear to be equivalent in restoring vaginal cytology and pH and relieving symptoms of vaginal dryness, pruritus, and dyspareunia; product selection should be based on patient preference.[74] Vaginal creams and tablets are initiated with once-daily dosing; after symptoms have resolved, the patient should be switched to maintenance dosing of once- or twice-weekly administration. The low-dose vaginal ring releases a constant dose of estrogen for 90 days.

The most common adverse effects of vaginal estrogens are vaginal irritation and bleeding and breast tenderness. Based on limited studies, the risk of endometrial hyperplasia from low-dose vaginal estrogen is small, and the addition of a progestogen is generally considered unnecessary.[74,78] Women at high risk for endometrial cancer, using higher than usual doses of vaginal estrogen, or experiencing vaginal bleeding during intravaginal ET, should be evaluated for endometrial hyperplasia.[74]

Because B.L. has not had relief with nonhormonal therapy, localized ET such as conjugated estrogen, 1 g of 0.625 mg/g cream, applied vaginally once daily is appropriate. After her symptoms have resolved, the dose can be decreased to a maintenance regimen of twice-weekly administration.

Thyroid Disorders

Eric F. Schneider and Betty J. Dong

CORE PRINCIPLES	CHAPTER CASES
① Thyroid function tests are essential to confirm the presence of thyroid disorders but can be altered by acute and chronic illness and certain drugs. Thyrotropin (TSH) is the most accurate indicator of euthyroidism.	**Case 52-1 (Questions 1, 2), Case 52-2 (Question 1), Case 52-3 (Question 1), Case 52-4 (Question 1), Case 52-5 (Question 5), Case 52-23 (Question 1), Case 52-24 (Question 1), Table 52-1 and 52-7 Figure 52-1 and 52-2**
② Thyroid hormone deficiency can cause a goiter and hypothyroid symptoms including myxedema coma, heart failure, and hyperlipidemia. The most common cause of hypothyroidism is Hashimoto's thyroiditis.	**Case 52-5 (Question 1), Case 52-8 (Question 2), Case 52-9 (Question 2), Case 52-10 (Question 1), Case 52-11 (Questions 1, 2), Case 52-12 (Question 1), Case 52-13 (Question 1), Case 52-20 (Question 1), Tables 52-2 and 52-3**
③ Generic or branded levothyroxine (L-thyroxine) is the preparation of choice for optimal correction of hypothyroidism. Triiodothyronine (T_3)-containing preparations are not necessary because thyroxine (T_4) is converted to T_3.	**Case 52-5 (Question 2), Case 52-6 (Question 1), Case 52-10 (Question 2), Tables 52-4 and 52-8**
④ The signs and symptoms of hypothyroidism can be corrected by the administration of l-thyroxine on an empty stomach at average oral replacement dosages of 1.6 to 1.7 mcg/kg/day or intravenously. Dosing is altered by weight, comorbidities, and drug interactions.	**Case 52-5 (Questions 3–5), Case 52-7 (Question 1), Case 52-8 (Question 1), Case 52-9 (Question 1), Case 52-10 (Question 2), Case 52-11 (Question 3), Table 52-4, 52-8 and 52-9**
⑤ The signs and symptoms of hyperthyroidism mimic those of adrenergic excess (e.g., tachycardia, tremors, thyroid storm), but symptoms in the elderly may be absent ("apathetic"). Graves' disease, a common cause	**Case 52-14 (Questions 1, 2), Case 52-15 (Question 1), Case 52-21 (Questions 1, 2),**

	of hyperthyroidism, can be complicated by ophthalmopathy.	**Case 52-22 (Questions 1, 2), Table 52-5 and 52-6, Figure 52-3**
6	Management of hyperthyroidism includes thioamides, iodides, radioactive iodine, and surgery. β-Blockers can provide symptomatic relief of hyperthyroid symptoms.	**Case 52-15 (Questions 2–9, 12), Case 52-16 (Question 1), Case 52-19 (Questions 1, 2), Case 52-20 (Question 1), Case 52-22 (Question 2), Table 52-10**

7	Methimazole is preferable to propylthiouracil except during the first trimester of pregnancy and during thyroid storm. Thioamide toxicity includes gastrointestinal symptoms, rash, agranulocytosis, and hepatitis.	**Case 52-15 (Questions 4–8, 10, 11), Case 52-18 (Question 1)**
8	Both hypothyroidism and hyperthyroidism can alter metabolism of coadministered medications (e.g., digoxin, warfarin).	**Case 52-14 (Questions 2, 3)**
9	The management of subclinical hypothyroidism and hyperthyroidism should be individualized.	**Case 52-12 (Question 1), Case 52-17 (Question 1)**
10	Certain drugs (e.g., amiodarone, interferon, lithium, tyrosine kinase inhibitors) can cause thyroid disorders.	**Case 52-23 (Question 1), Case 52-24 (Question 1), Table 52-2 and 52-6**

OVERVIEW

Thyroid disease, including hypothyroidism, hyperthyroidism, and nodular disease, is common, affecting 5% to 15% of the general population. Women are affected 3 to 4 times more than men. Triiodothyronine (T_3) and thyroxine (T_4) are the two biologically active thyroid hormones produced by the thyroid gland. The hypothalamic thyrotropin-releasing hormone (TRH) stimulates release of thyrotropin (i.e., thyroid-stimulating hormone [TSH]) from the pituitary in response to low circulating levels of thyroid hormone. TSH in turn promotes hormone synthesis and release by increasing thyroid activity. High circulating thyroid hormone levels block further production by inhibiting TSH release (negative feedback). As the serum concentrations of thyroid hormone decrease, the hypothalamic-pituitary centers again become responsive by releasing TRH and TSH (Fig. 52-1).

T_3 is 4 times more potent than T_4, the major circulating hormone secreted by the thyroid. About 80% of the total daily T_3 production results from the peripheral deiodination of T_4 to T_3 Approximately 35% to 40% of secreted T_4 is converted peripherally to T_3; another 45% of secreted T_4 undergoes peripheral conversion to inactive reverse T_3 (rT_3). Certain drugs and diseases can modify the conversion rate of T_4 to T_3 and reduce the serum T_3 levels (Table 52-1[1,2]; see Case 52-1, Question 2).

T_4 exists in the circulation as 0.03% free (active) and 99.97% protein-bound (inactive), primarily to thyroxine-binding globulin (TBG). This affinity for plasma proteins accounts for T_4's slow metabolic degradation and long half-life ($t_{1/2}$) of 7 days. T_3 is less strongly bound to plasma proteins (99.7%); with about 0.3% free. The lower protein-binding affinity of T_3 accounts for its threefold greater metabolic potency and its shorter $t_{1/2}$ of 1.5 days.

Hypothyroidism is a clinical syndrome that results from a deficiency of thyroid hormone. The prevalence of hypothyroidism is 1.4% to 2% in women and 0.1% to 0.2% in men and is increased in persons older than 60 years, to 6% of women and 2.5% of men. Hypothyroidism can be caused by either primary (thyroid gland) or less commonly, by secondary (hypothalamic-pituitary) malfunction.

Hashimoto's thyroiditis, an autoimmune disorder, is the most common cause of primary hypothyroidism and appears to have a strong genetic predisposition. The pathogenesis of Hashimoto's thyroiditis results from an impaired immune surveillance, causing dysfunction of normal suppressor T lymphocytes and excessive production of thyroid antibodies by plasma cells (differentiated B lymphocytes). The destruction of thyroid cells by circulating thyroid antibodies produces an underlying defect or block in the intrathyroidal, organobinding of iodide. The typical presentation is hypothyroidism and goiter (thyroid gland enlargement), but patients can present with hypothyroidism and no goiter, with euthyroidism and goiter, or rarely (<5%) with hyperthyroidism (Hashitoxicosis).

Other common causes of hypothyroidism, including drug induced, are presented in Table 52-2[3–24]

The clinical presentation, physical findings, and laboratory abnormalities of overt hypothyroidism are summarized in Table 52-3. Myxedema coma is a medical emergency resulting from longstanding, uncorrected hypothyroidism (see Case 52-10). Patients with myxedema coma can present with hypothermia, confusion, coma, carbon dioxide retention, hypoglycemia, hyponatremia, and ileus. Hypothyroid symptoms increase with the severity of the hypothyroidism except in the older patient, who often presents with minimal or atypical symptoms. Patients with subclinical hypothyroidism might have few or no symptoms. Laboratory findings that are diagnostic for overt hypothyroidism include elevated TSH and low free thyroxine (FT_4) levels; for subclinical or early hypothyroidism, the findings are an elevated TSH and normal FT_4 levels.

Levothyroxine (L-thyroxine), at an oral replacement dosage of 1.6 to 1.7 mcg/kg/day administered on an empty stomach, is the preferred thyroid replacement preparation. Several brand name and less costly generic preparations are interchangeable in most patients. Older patients, and those with severe hypothyroidism, and cardiac disease may require minute T_4 doses initially to avoid cardiac toxicity (Table 52-4); complete reversal of hypothyroidism might not be indicated or possible. In myxedema coma, an intravenous (IV) L-thyroxine (e.g., 400 mcg × 1) loading dose is necessary to reduce the high mortality rate. In subclinical hypothyroidism (see Case 52-12), T_4 replacement therapy is beneficial in those with TSH >10 IU/mL.

Table 52-1

Factors that can Significantly Alter Thyroid Function Tests in Euthyroid Patients

Factors	Drugs/Situations
↑ TBG Binding Capacity	
↑ TT_4	Estrogens,[1,2] tamoxifen,[55] raloxifene[54]
↑ TT_3	Oral contraceptives[21]
Normal TSH	Heroin[53]
Normal FT_4I, FT_4	Methadone maintenance[53]
Normal FT_3I, FT_3	Genetic ↑ in TBG
	Clofibrate
	Active hepatitis[31]
↓ TBG Binding Capacity/Displacement T4 from Binding Sites	
↓ TT_4	Androgens[21]
↓ TT_3	Salicylates,[21,45,46] disalcid,[46] salsalate[46]
Normal TSH	High-dose furosemide
Normal FT_4I, FT_4	↓ TBG synthesis-cirrhosis/hepatic failure
Normal FT_3I, FT_3	Nephrotic syndrome[21,31]
	Danazol[21,31]
	Glucocorticoids[21,31,59]
↓ Peripheral T4 → T3 Conversion	
↓ TT_3	PTU
Normal TT_4	Propranolol[200]
Normal FT_4I, FT_4	Glucocorticoids[21,33,59]
Normal TSH	
↓ Pituitary and Peripheral T4 → T3	
↓ TT_3	Iodinated contrast media (e.g., ipodate)[249–253]
↑ TT_4	Amiodarone[3,12,17]
↑ TSH (transient)	Non-thyroidal illness[37,39,254]
↑ FT_4I	
↑ T4 Clearance by Enzyme Induction/↑ Fecal Loss[a]	
↓ TT_4	Phenytoin[47,48]

↓ FT$_4$I	Phenobarbital[47]
Normal or ↓ FT$_4$	Carbamazepine[47–52]
Normal or ↓ TT$_3$	Cholestyramine, colestipol[127]
Normal or ↑ TSH	Rifampin[47]
	Bexarotene[20]
↓ TSH Secretion	
	Dopamine[21,31] dobutamine[255]
	Levodopa[21] cabergoline[256]
	Glucocorticoids[21,33,59]

↑ TSH Secretion	
	Metoclopramide[21,31,33]
	Domperidone[21,31,33]

[a] Can also cause hypothyroidism in patients receiving levothyroxine therapy.

FT$_3$, free triiodothyronine; FT$_4$, free thyroxine; FT$_3$I, free triiodothyronine index; FT$_4$I, free thyroxine index; PTU, propylthiouracil; T$_3$, triiodothyronine; T$_4$, thyroxine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; TT$_3$, total triiodothyronine; TT$_4$, total thyroxine.

Table 52-2

Causes of Hypothyroidism

Non-goitrous (No Gland Enlargement)
Primary Hypothyroidism (Dysfunction of the Gland)
Idiopathic atrophy
Iatrogenic destruction of thyroid
Surgery
Radioactive iodine therapy
X-ray therapy
Postinflammatory thyroiditis
Cretinism (congenital hypothyroidism)
Secondary Hypothyroidism
Deficiency of TSH because of pituitary dysfunction
Deficiency of TRH because of hypothalamic dysfunction
Goitrous Hypothyroidism (Enlargement of Thyroid Gland)
Dyshormonogenesis: defect in hormone synthesis, transport, or action
Hashimoto’s thyroiditis

Congenital cretinism: maternally induced
Iodide deficiency
Natural goitrogens: rutabagas, turnips, cabbage
Drug-Induced
Aminoglutethimide[21]
Amiodarone[3,12,17]
Bexarotene[10,20]
Ethionamide[18]
Iodides and iodide-containing preparations[16]
Rifampin[22]
Tyrosine kinase inhibitors (e.g., imatinib, sunitinib, sorafenib)[8,9,14,19]
Interleukin[11,23]
Interferon-α [6,7,15,24]
Lithium[4,5,13]
Thiocyanates, phenylbutazone, sulfonylureas[21]

TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

The goal of therapy is to reverse the signs and symptoms of hypothyroidism and normalize the TSH and FT_4 levels. Some improvement of hypothyroid symptoms is often evident within 2 to 3 weeks of starting T_4 therapy. Over-replacement of T_4 (i.e., suppressed serum concentrations of TSH) is associated with osteoporosis and cardiac toxicity. The optimal T_4 replacement dosage must be administered for approximately 6 to 8 weeks to achieve steady-state levels. Medications that interfere with T_4 absorption (e.g., iron, aluminum-containing products, some calcium preparations [e.g., carbonate], cholesterol resin phosphate binders, and raloxifene) should be separated by at least 4 hours from concomitant T_4 administration.

Table 52-3

Clinical and Laboratory Findings of Primary Hypothyroidism

Symptoms	Physical Findings	Laboratory
General: weakness, tiredness, lethargy, fatigue	Thin brittle nails	↓ TT_4
Cold intolerance	Thinning of skin	↓ FT_4I
Headache	Pallor	↓ FT_4
Loss of taste/smell	Puffiness of face, eyelids	↓ TT_3

Deafness	Yellowing of skin	↓ FT_3I
Hoarseness	Thinning of outer eyebrows	↑ TSH
No sweating	Thickening of tongue	Positive antibodies (in Hashimoto’s)
Modest weight gain	Peripheral edema	↑ Cholesterol
Muscle cramps, aches, pains	Pleural/peritoneal/pericardial effusions	↑ CPK
Dyspnea	↓ DTRs	↓ Na
Slow speech	“Myxedema heart”	↑ LDH
Constipation	Bradycardia (↓ HR)	↑ AST
Menorrhagia	Hypertension	↓ Hct/Hgb
Galactorrhea	Goiter (primary hypothyroidism)	

AST, aspartate aminotransferase; CPK, creatinine phosphokinase; DTRs, deep tendon reflexes; Hct, hematocrit; Hgb, hemoglobin; HR, heart rate; LDH, lactate dehydrogenase; Na, sodium; FT_3I, free triiodothyronine index; FT_4I, free thyroxine index; FT_4, free thyroxine; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine.

Table 52-4

Treatment of Hypothyroidism

Patient Type/Complications	Dose (L-Thyroxine)	Comment
Uncomplicated adult	1.6–1.7 mcg/kg/day; 100–125 mcg/day average replacement dose; usual increment 25 mcg q6–8wk	2–3 weeks; 4–6 weeks. Reversal of skin and hair changes may take several months. An FT_4 and TSH should be checked 6–8 weeks after initiation of therapy because T_4 has a half-life of 7 days and three to four half-lives are needed to achieve steady state. Levels obtained before steady state can be very misleading. Because 80% is bioavailable, adjust IV doses downward. Small changes can be made by varying dose schedule (e.g., 150 mcg daily except Sunday).
Elderly	≤1.6 mcg/kg/day (50–100 mcg/day)	Initiate T_4 cautiously. Elderly may require less than younger patients. Sensitive to small dose changes. A few patients older than 60 years require ≤50 mcg/day.
Cardiovascular disease (angina, CAD)	Start with 12.5–25 mcg/day. ↑ by 12.5–25 mcg/day q2–6 weeks as tolerated	These patients are very sensitive to cardiovascular effects of T_4. Even subtherapeutic doses can precipitate severe angina, MI, or death. Replace thyroid deficit slowly, cautiously, and sometimes even suboptimally.
Long-standing hypothyroidism (>1 year)	Dose slowly. Start with 25 mcg/day. ↑ by 25 mcg/day q4–6 weeks as tolerated	Sensitive to cardiovascular effects of T_4. Steady state may be delayed because of ↓ clearance of T_4.[a] Correct replacement dose is a compromise between prevention of myxedema and avoidance of cardiac toxicity.
Pregnancy	Most will require 45% ↑ in dose	Evaluate TSH, TT_4, and FT_4I. normal TSH and

	to ensure euthyroidism	TT_4/FT_4I in upper normal range to prevent fetal hypothyroidism. TSH should be no higher than 2.5 microunits/mL during the first trimester and 3.0 microunits/mL in the second and third trimesters
Pediatric (0–3 mo)	10–15 mcg/kg/day	Hypothyroid infants can exhibit skin mottling, lethargy, hoarseness, poor feeding, delayed development, constipation, large tongue, neonatal jaundice, piglike facies, choking, respiratory difficulties, and delayed skeletal maturation (epiphyseal dysgenesis). The serum T_4 should be increased rapidly to minimize impaired cognitive function. In the healthy term infant, 37.5–50 mcg/day of T_4 is appropriate. Dose decreases with age (Table 52-9).

[a] In severely myxedematous patients, steady state may require ≥6 months. In patients who are clinically euthyroid but have ↑ TT_4 and FTI, use TT_3 and TSH as guide to dose adjustments.

CAD, coronary artery disease; FT_4, free thyroxine; FT_4I, free thyroxine index; IV, intravenous; MI, myocardial infarction; q, every; QD, every day; T_4, thyroxine; TSH, thyroid-stimulating hormone; TT_4, total thyroxine.

Hyperthyroidism or thyrotoxicosis is the hypermetabolic syndrome that occurs from excessive thyroid hormone production. Hyperthyroidism affects about 2% of women and about 0.1% of men. The prevalence in older patients varies between 0.5% and 2.3% but accounts for 10% to 15% of all thyrotoxic patients.

The classic symptoms of hyperthyroidism are summarized in Table 52-5. The typical symptoms are often absent in the older patient, producing a masked or “apathetic” picture. Because of the atypical presentation in the older patient, occult hyperthyroidism always must be considered, especially in patients with new or worsening cardiac findings (e.g., atrial fibrillation). Untreated hyperthyroidism can progress to thyroid storm, a life-threatening form of hyperthyroidism characterized by exaggerated symptoms of thyrotoxicosis and the acute onset of high fever. The diagnosis of hyperthyroidism is confirmed by high serum concentrations of FT_4 and free T_3 (FT_3) or an undetectable TSH level. Positive thyroid antibodies confirm an autoimmune origin for the hyperthyroidism (e.g., Graves’ disease).

Table 52-5

Clinical and Laboratory Findings of Hyperthyroidism

Symptoms
Heat intolerance
Weight loss common, or weight gain caused by ↑ appetite
Palpitations
Pedal edema

Diarrhea/frequent bowel movements
Amenorrhea/light menses
Tremor
Weakness, fatigue
Nervousness, irritability, insomnia
Physical Findings
Thinning of hair (fine)
Proptosis, lid lag, lid retraction, stare, chemosis, conjunctivitis, periorbital edema, loss of extraocular movements
Diffusely enlarged goiter, bruits, thrills
Wide pulse pressure
Pretibial myxedema
Plummer's nails[a]
Flushed, moist skin
Palmar erythema
Brisk DTRs
Laboratory Findings
↑ TT_4
↑ TT_3
↑ FT_4I/FT_4
↑ FT_3I/FT_3
Suppressed TSH
TSI present
TgAb present
TPOAb present
RAIU >50%
↓ Cholesterol
↑ Alkaline phosphatase
↑ Calcium
↑ AST

[a] The fingernail separates from its matrix, but only one or two nails are generally affected.

AST, aspartate aminotransferase; TgAb, thyroglobulin autoantibodies; DTRs, deep tendon reflexes; FT_3, free triiodothyronine; FT_4, free thyroxine; FT_3I, free triiodothyronine index; FT_4I, free thyroxine index; RAIU, radioactive iodine uptake; TPOAb, thyroid peroxidase antibody; TSI, thyroid-stimulating immunoglobulin; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine.

Graves' disease, an autoimmune disease, is the most common cause of hyperthyroidism. Characteristics include diffuse goiter, ophthalmopathy (exophthalmos), dermopathy (pretibial myxedema), and acropachy (thickening of fingers or toes). The production of excessive thyroid hormone is attributed to a circulating immunoglobulin G or thyroid receptor antibody (TRAb), which has a TSH-like ability to stimulate hormone synthesis. The abnormal production of TRAb by plasma cells (differentiated B lymphocytes) results from a deficiency of suppressor T-cell lymphocytes. Other causes of hyperthyroidism, including iatrogenic, are outlined in Table 52-6.[3,11,12,15,17,21,24–28]

Both Graves' disease and Hashimoto's thyroiditis share similar clinical features and can exist in the same gland: positive antibody titers, goiter with lymphocytic infiltration of the gland, familial tendency, and predilection for women. Thyrotoxicosis can precede the onset of Hashimoto's hypothyroidism, and the end result of Graves' hyperthyroidism is often hypothyroidism.

Effective treatment options for hyperthyroidism include thioamides, radioiodine, and surgery. Therapy selection is influenced by the etiology of the hyperthyroidism, size of the goiter, presence of ophthalmopathy, coexisting conditions (e.g., angina, pregnancy), patient age, patient preference, and physician bias. Radioactive iodine (RAI) is preferred in older patients, those with coexisting cardiac disease, ophthalmopathy, and a toxic multinodular goiter, whereas surgery is appropriate if obstructive symptoms are present or concomitant malignancy is suspected. Pregnant patients can be managed with thioamides or surgery in the second trimester; RAI is absolutely contraindicated.

The thioamides (e.g., methimazole, propylthiouracil) primarily prevent hormone synthesis but do not affect existing stores of thyroid hormone. Therefore, hyperthyroid symptoms will continue for 4 to 6 weeks after beginning thioamide therapy, and initial treatment with β-blockers or iodides is often required for symptomatic relief. Methimazole, given once daily, is considered the thioamide of choice versus propylthiouracil (PTU), which requires 2 to 3 times daily dosing and has been associated with severe and fatal hepatitis. PTU should be reserved for use during the first trimester of pregnancy, in thyroid storm, and in those experiencing adverse reactions to methimazole (other than agranulocytosis or hepatitis). The onset of action of PTU is more rapid than methimazole in thyroid storm because PTU can also inhibit the peripheral conversion of T_4 to T_3. PTU is also preferred during the first trimester of pregnancy because congenital defects have been reported with methimazole. Although both drugs are secreted in breast milk, no adverse effects have been reported in the exposed infants. The duration of treatment is empiric, and thioamides typically are prescribed for 12 to 18 months in hopes of long-term spontaneous remission once the drug is discontinued. Although thioamides maintain euthyroidism, they do not change the natural course of the disease, and the likelihood of spontaneous remission, once treatment is discontinued, is about 60%. The combination of thioamide and T_4 therapy to increase the likelihood of remission is not effective nor recommended. Major adverse effects from thioamides include skin rash, gastrointestinal (GI) complaints (e.g., nausea, upset stomach, and metallic taste), agranulocytosis, and hepatitis. Cross-sensitivity between the thioamides is not complete, and the alternative drug can be used if rash or GI complaints do not resolve. This is not true for agranulocytosis and hepatitis, and the alternative agent is not recommended.

Table 52-6

Causes of Hyperthyroidism

Graves' disease (toxic diffuse goiter); may be caused by polymorphisms in the TSH receptor[27]
Toxic uninodular goiter (Plummer's disease)
Toxic multinodular goiter
Nodular goiter with hyperthyroidism caused by exogenous iodine (Jod-Basedow)
Exogenous thyroid excess through self-administration (factitious hyperthyroidism)
Tumors (thyroid adenoma, follicular carcinoma, thyrotropin-secreting tumor of the pituitary, and hydatidiform mole with secretion of a thyroid-stimulating substance)
Drug induced (iodides,[28]amiodarone,[3,12,17] interleukin,[11,21] interferon-α,[15,24] lithium[25,26])

Nodular goiters, both multinodular and uninodular, are common thyroid problems that occur in 4% to 5% of the adult population. The nodular goiter is usually found on routine physical examination in asymptomatic and euthyroid patients. A cold nodule is a "hypofunctioning" area of the thyroid that fails to collect radioiodine. Hot nodule is a term used to describe a "hyperfunctioning" or iodine-concentrating area of the thyroid. The hyperfunctioning autonomous nodule typically suppresses activity in the remainder of the gland, but it does not produce clinical or chemical evidence of hyperthyroidism and may remain unchanged for years. Some nodules may develop into toxic goiters, causing overt symptoms of toxicosis. Most hot nodules are benign; malignancies are rarely reported.[29] Treatment options include surgery, RAI, or thyroid replacement therapy if hypothyroid. All goitrogens should be removed if possible. L-Thyroxine suppression therapy is no longer recommended because the dangers from supraphysiologic dosages of T_4 (e.g., osteoporosis and the potential for cardiac arrhythmias) outweigh the benefits. Nontoxic multinodular goiter is a common finding in about 5% of the population.[29] In low-risk patients, long-standing asymptomatic nodules that have not exhibited recent growth are likely to be benign and can be followed or excised surgically for cosmetic reasons. If the patient develops symptoms (swallowing or respiratory difficulty), surgery is the treatment of choice. Observation with close follow-up is the preferred treatment option for most benign multinodular goiters.[29]

Malignancy must be considered if there is recent growth in a "cold" single or dominant nodule, a firm nodule clinically suspicious for cancer on a physical examination, a history of thyroid irradiation, or a strong family history of medullary thyroid carcinoma. Most cold nodules turn out to be benign adenomas rather than cancers. The incidence of malignancy in a cold nodule varies between 10% and

20%.[30] A fine needle aspiration (FNA) of the thyroid nodule can document an underlying malignancy. Surgery is indicated if malignancy is suspected or if any obstructive or respiratory symptoms are present. After a total thyroidectomy for thyroid cancer, RAI ablation is usually given to remove any remaining thyroid tissue. A yearly evaluation for detection of recurrence of some thyroid cancers requires the patient to be off T_4 for 4 to 6 weeks, so that a repeat radioactive uptake and scan can be completed. An elevated TSH level is also necessary to allow thyroglobulin levels, a tumor marker, to rise if any malignant tissue is present. The administration of recombinant human TSH may improve quality of life because comparable elevations in TSH occur without stopping L-thyroxine therapy, reducing the duration of hypothyroidism.

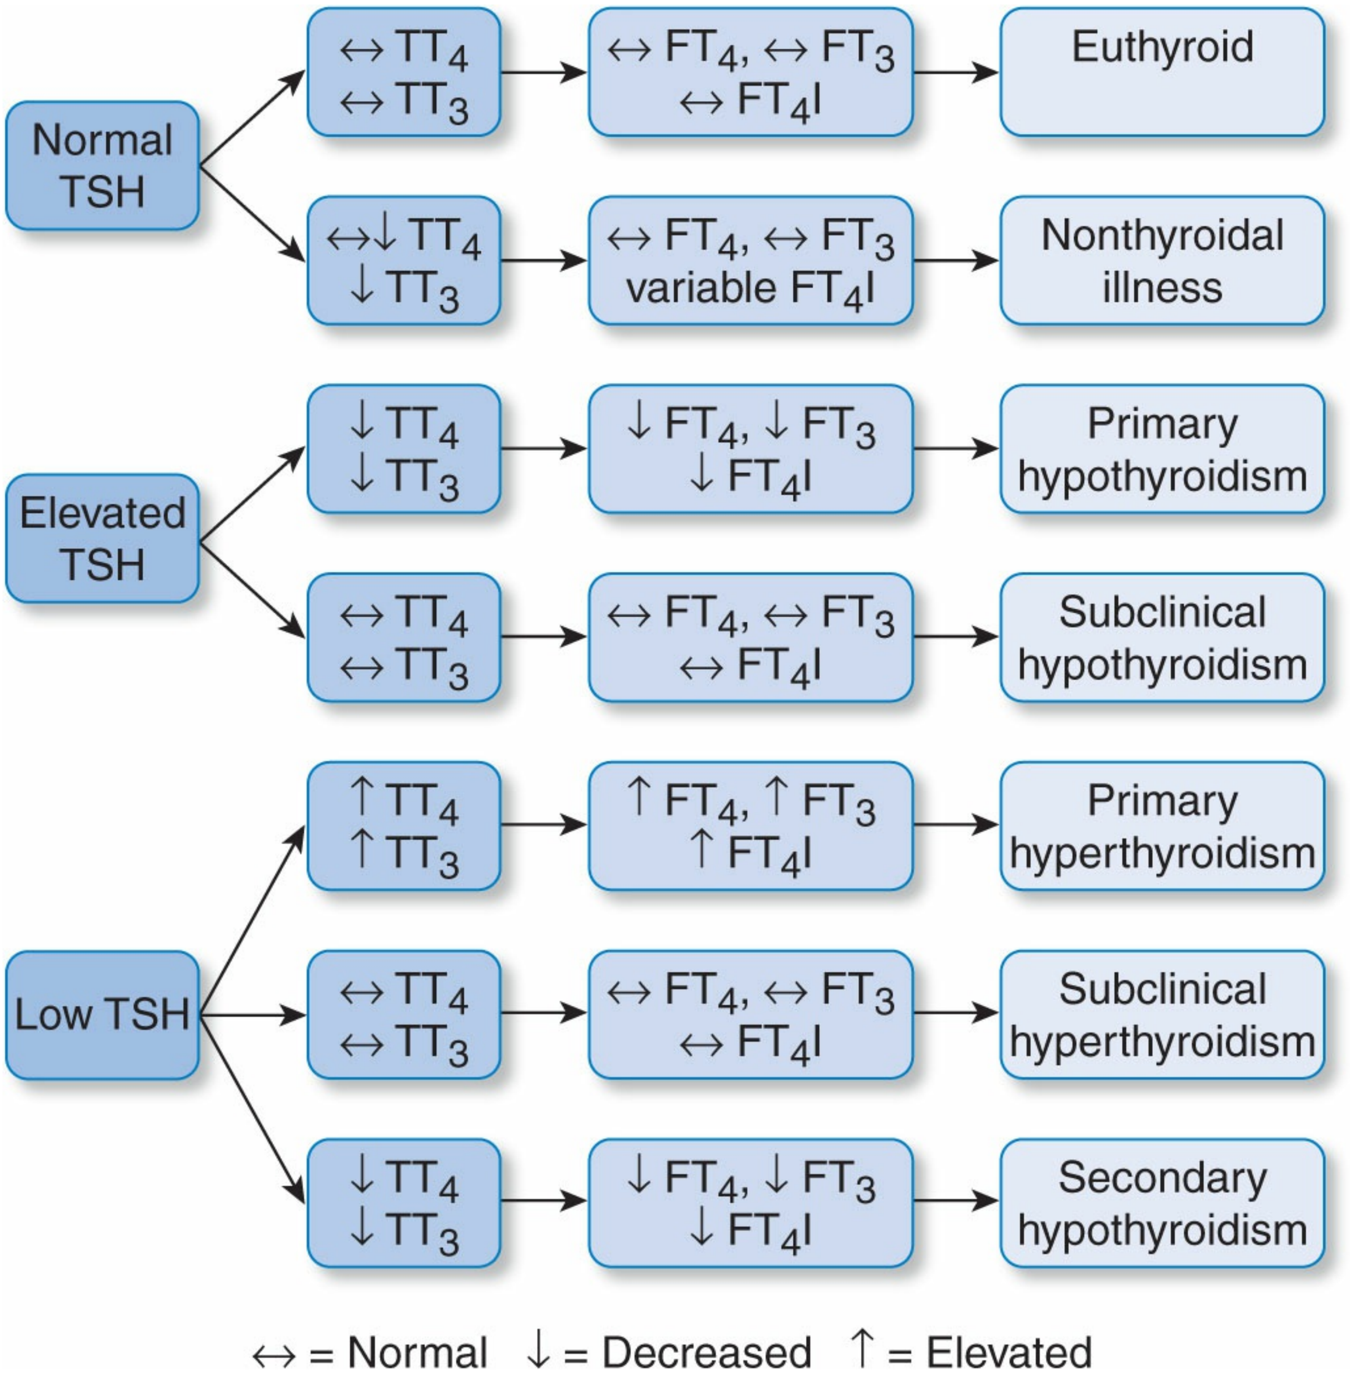
THYROID FUNCTION TESTS

The principal laboratory tests recommended in the initial evaluation of thyroid disorders are the TSH and the FT_4 levels.[31–33] The relationship between laboratory tests and thyroid disorders is summarized in Figure 52-2. The presence of thyroid antibodies indicates an autoimmune thyroid etiology. Adjuncts to the previous tests include the total T_3 (TT_3), free T_3 (FT_3) or FT_3 index (FT_3I), RAIU and scan, TRAb, ultrasound, and FNA biopsy (Table 52-7).

Measurements of Free and Total Serum Hormone Levels

FREE THYROXINE, FREE THYROXINE INDEX, FREE TRIIODOTHYRONINE, AND FREE TRIIODOTHYRONINE INDEX

The free thyroxine (FT_4) and free triiodothyronine (FT_3) are the most reliable tests for the evaluation of hormone concentrations, especially when thyroid hormone–binding abnormalities exist. The FT_3 is most useful in hyperthyroidism but can be normal or low in hypothyroidism. If a direct measure of the free hormone levels is not available, the estimated free hormone indices (FT_4I, FT_3I) can provide comparable information. However, these indices do not correct for changes observed in patients with “euthyroid sick” non-thyroidal illnesses in whom TBG-binding affinity is altered. In these circumstances, the FT_4 and FT_3 are preferable.[34,35]



Normal TSH
↔ TT4 ↔ TT3
↔ FT4, ↔ FT3 ↔ FT4I
Euthyroid
↔↓ TT4 ↓ TT3
↔ FT4, ↔ FT3 variable FT4I
Nonthyroidal illness
Elevated TSH

Table 52-7

Common Thyroid Function Tests

Tests	Measures	Normal[a]	Assay Interference	Comments
Measurement of Circulating Hormone Levels				
	Direct measurement	0.8–1.4 ng/dL (10–	No interference by	Most accurate

FT$_4$	of free thyroxine	18 pmol/L)	alterations in TBG	determination of FT$_4$ levels; might be higher than normal in patients on thyroxine replacement
FT$_4$I	Calculated free thyroxine index	T$_4$ uptake method: 6.5–12.5 TT$_4$ × RT$_3$U method: 1.3–4.2	Non-thyroidal illness (see question 2)	Estimates direct FT$_4$ measurement; compensates for alterations in TBG
TT$_4$	Total free and bound T$_4$	4.8–10.4 mcg/dL (62–134 mmol/L)	Alterations in TBG (Table 52-1)	Specific and sensitive test if no alterations in TBG
TT$_3$	Total free and bound T$_3$	58–201 ng/dL (0.9–3.1 nmol/L)	Alterations in TBG levels; T$_4$ to T$_3$ (Table 52-1). Non-thyroidal illness (see question 2)	Useful in detecting early, relapsing, and T$_3$ toxicosis. Not useful in evaluation of hypothyroidism
FT$_3$	Direct measurement of free T$_3$	168–370 pg/dL (2.6–5.7 pmol/L)	No interference by alterations in TBG	Most accurate determination of FT$_4$ levels; might be lower than normal in patients on thyroxine replacement
FT$_3$I	Calculated free T$_3$ index	17.5–46	Non-thyroidal illness (see question 2)	Estimates direct FT$_3$ measurement; compensates for alterations in TBG
Tests of Thyroid Gland Function				
RAIU	Gland's use of iodine after trace dose of either ^{123}I or ^{131}I	5%–35%	False decrease with excess iodide intake; false elevation with iodide deficiency	Useful in hyperthyroidism to determine RAI dose in Graves'; does not provide information regarding hormone synthesis
Scan	Gland size, shape, and tissue activity after ^{123}I or ^{99m}Tc	–	^{154}I scan blocked by antithyroid/thyroid medications	Useful in nodular disease to detect "cold" or "hot" areas
Test of Hypothalamic–Pituitary–Thyroid Axis				
TSH	Pituitary TSH level	0.45–4.1 microunits/mL	Dopamine, glucocorticoids, metoclopramide, thyroid hormone, amiodarone, metformin (Table 52-1)	Most sensitive index for hyperthyroidism, hypothyroidism, and replacement therapy
Tests of Autoimmunity				
TgAb	Thyroglobulin Autoantibodies (ultrasensitive)	<2 IU/mL	Non-thyroidal autoimmune disorders	Present in autoimmune thyroid disease; undetectable during remission
TPOAb	Thyroid peroxidase antibodies	<100 WHO units	Non-thyroidal autoimmune	More sensitive of the two antibodies; titers

			disorders	detectable even after remission
TSI	Thyroid stimulating antibody	<140%		Confirms Graves' disease; detects risk of neonatal Graves'
TRAb	Thyroid receptor antibody	<1.75 IU/L		Confirms Graves' disease; detects risk of neonatal Graves'
Miscellaneous				
Thyroglobulin	Colloid protein of normal thyroid gland	<29.2 µg/L (male) <38.5 µg/L (female)	Goiters; inflammatory thyroid disease	Marker for recurrent thyroid cancer or metastases in thyroidectomized patients

[a] At University of California laboratories.

TgAb, thyroglobulin auto antibodies; FT_3, free triiodothyronine; FT_4, free thyroxine; FT_3I, free triiodothyronine index; FT_4I, free thyroxine index; RAI, radioactive iodine; RAIU, radioactive iodine uptake; T_3, triiodothyronine; T_4, thyroxine; TBG, thyroxine-binding globulin; TPOAb, thyroid peroxidase antibodies; TSI, thyroid receptor–stimulating or thyroid-stimulating antibodies; TRAb, thyroid receptor antibody; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine; T_3RU, Triiodothyronine resin uptake.

TOTAL THYROXINE AND TOTAL TRIIODOTHYRONINE

The total thyroxine (TT_4) and total triiodothyronine (TT_3) measure both free and bound (total) serum T_4 and T_3. Because the bound fraction is the major fraction measured, situations that change the hormone's affinity for TBG or the TBG level will influence the results. For example, falsely elevated levels of TT_4 and TT_3 are common in the euthyroid pregnant woman (see Case 52-3). In addition, the TT_3 is often low in older patients and in many acute and chronic non-thyroidal illnesses because the peripheral conversion of T_4 to T_3 is decreased (see Case 52-1, Question 2 and Case 52-2). Therefore, careful interpretation of these tests is necessary in situations that alter thyroid hormone binding, TBG levels, or T_4 to T_3 conversion (Table 52-1). The TT_3 (and FT_3) is particularly helpful in detecting early relapse of Graves' disease and in confirming the diagnosis of hyperthyroidism despite normal TT_4 levels. Conversely, TT_3 and FT_3 are not good indicators of hypothyroidism because T_3 levels can be normal. Measurement of only the total hormone levels is less reliable than either the free or estimated free hormone levels when alterations in thyroid-binding globulin or non-thyroidal illnesses exist.[34,35]

Tests of the Hypothalamic–Pituitary–Thyroid Axis

THYROID-STIMULATING HORMONE OR THYROTROPIN

The serum thyroid-stimulating hormone or thyrotropin (TSH) is the most sensitive test to evaluate thyroid function.[31–33] TSH, secreted by the pituitary, is elevated in early or subclinical hypothyroidism (when thyroid hormone levels appear normal) and when thyroid hormone replacement therapy is inadequate. TSH can be abnormal even if the FT_4 remains within the normal range because the TSH is specific for each person's physiologic set point. Polymorphisms in the TSH receptor contribute to this interindividual variability.[27] Consequently, low normal free hormone levels can stimulate the pituitary to synthesize increased amounts of TSH. TSH cannot differentiate between primary hypothyroidism (thyroid failure), which is characterized by elevated TSH levels, and secondary (pituitary or hypothalamus failure) hypothyroidism where TSH levels may be low or normal. The TSH assay can quantitate the upper and lower limits of normal, so that a suppressed TSH level is highly suggestive of hyperthyroidism or exogenous thyroid overreplacement. Of note, TSH is not entirely specific for thyroid disease because abnormal levels are observed in euthyroid patients with non-thyroidal illnesses and in patients receiving drugs that can interfere with TSH secretion. TSH secretion is increased at bedtime and is affected by lack of sleep and exercise.[36] TSH secretion is suppressed physiologically by dopamine, which antagonizes the stimulatory effects of TRH. Therefore, both dopaminergic agonists and antagonists can alter TSH secretion (see Case 52-4). Whether the upper limits of normal for TSH should be lowered to 2.5 microunits/mL is controversial.[27,36]

Tests of Gland Function

RADIOACTIVE IODINE UPTAKE

The radioactive iodine uptake (RAIU), a measure of iodine utilization by the gland, is an indirect measure of hormone synthesis. It is elevated in hyperthyroidism and in early hypothyroidism when the failing gland is trying to increase hormone synthesis. A low or undetectable RAIU occurs in hypothyroidism, thyrotoxicosis factitia, and subacute thyroiditis. Typically, RAIU is used to calculate the dose of RAI therapy for treatment of Graves' disease and to determine the activity of one or several nodules in a gland. The RAIU is not necessary to diagnose classic Graves' disease or hypothyroidism.

A tracer dose of iodine-131 (^{131}I) is administered, and the radioactivity of the gland is measured at 5 and 24 hours after ingestion. It is necessary to measure both the 5- and 24-hour RAIU, so that patients with rapid turnover of iodine will not be missed. In some hyperthyroid patients, the 5-hour uptake is elevated, but the 24-hour uptake can fall to normal or subnormal levels. The normal range of the RAIU (Table 52-7) is affected by any condition that alters iodine intake. Iodine depletion caused by rigorous diuretic therapy or an iodine-deficient diet increases uptake because of replenishment of depleted total iodide pools. Conversely, dilution of ^{131}I with exogenous iodide sources (e.g., contrast dyes) decreases RAIU.

IMAGING STUDIES

Thyroid Scan

A scan of the gland is performed simultaneously with the RAIU or after ingestion of technetium (^{99m}Tc) pertechnetate. The scan provides information concerning gland size and shape, and identifies hypermetabolic ("hot") and hypometabolic ("cold") areas. The possibility of carcinoma must be considered if cold areas are present. A scan is often obtained in the evaluation of a patient with nodular thyroid disease.

Thyroid Ultrasound

A thyroid ultrasound can provide information about gland size and number of clinically palpable or non-palpable nodules or cysts in the thyroid gland.

Tests of Autoimmunity

THYROID PEROXIDASE AND ANTITHYROGLOBULIN ANTIBODIES

Thyroid peroxidase antibodies (TPOAb) and thyroglobulin autoantibodies (TgAb) to the thyroid gland indicate an autoimmune process.[31,33] About 60% to 70% of patients with Graves' disease and 95% of patients with Hashimoto's thyroiditis have positive antibodies to both thyroid antigens. Positive antibodies alone do not indicate thyroid disease because 5% to 10% of asymptomatic patients, as well as patients with other non-thyroidal autoimmune disorders, have positive antibodies.

Clinically, the TPOAb is more specific than TgAb in assessing disease activity. Although both antibodies are elevated during acute flares of the disease, lower titers of TPOAb remain positive during quiescent periods of the disease, while TgAb levels revert to negative.

THYROID RECEPTOR–STIMULATING ANTIBODIES OR THYROID-STIMULATING IMMUNOGLOBULIN

Thyroid receptor–stimulating antibodies (TRAb) or thyroid-stimulating immunoglobulin (TSI) are IgG immunoglobulins that are present in virtually all patients with Graves' disease.[31,33] Like TSH, these immunoglobulins can stimulate the thyroid gland to produce thyroid hormones. High titers of TSI are useful in diagnosing otherwise asymptomatic Graves' disease (i.e., ophthalmopathy), in predicting the risk of relapse of Graves' disease after discontinuing medication, and in predicting the risk of neonatal hyperthyroidism in utero through transplacental passage of TSI from the pregnant mother. Otherwise, TSI measurement is expensive and offers no additional information in the patient with a typical Graves' disease presentation.

Clinical Application and Interpretation

EUTHYROIDISM AND NON-THYROIDAL ILLNESS SYNDROME

CASE 52-1

QUESTION 1: R.K., an obese 42-year-old woman, is admitted to the hospital because of increasing fatigue, sluggishness, shortness of breath (SOB), and pitting edema of the legs during the past 3 weeks. Bilateral pleural effusions found on her chest radiograph indicate a worsening of her congestive heart failure (CHF). Her other medical problems include cirrhosis of the liver, type 2 diabetes, and chronic bronchitis, for which she takes glipizide 10 mg every day and an iodine-containing herbal supplement 3 times a day (TID).

Pertinent physical findings include a palpable but normal-size thyroid, bibasilar rales, cardiomegaly, hepatomegaly, 4 + pitting edema, and normal deep tendon reflexes (DTRs). A diagnosis of worsening CHF secondary to hypothyroidism is suspected based on the following laboratory findings:

Cholesterol, 385 mg/dL
RAIU at 24 hours, 13% (normal, 5%–35%[1])
Scan, normal-size gland with homogenous uptake
TT_4, 1.4 mcg/dL (normal, 4.8–10.4 mcg/dL)
TT_3, 22 ng/dL (normal, 58–201 ng/dL)
TSH, 4 microunits/mL (normal, 0.45–4.1 microunits/mL)
FT_4, 1.0 ng/dL (normal, 0.8–1.4 ng/dL)
TPOAb, 30 WHO units (normal, <100 WHO units)
TgAb, 0.3 IU/mL (normal, <2 IU/mL)

Evaluate and explain R.K.'s thyroid status based on her clinical and laboratory findings.

Although low-output failure can be a presenting sign of hypothyroidism, the normal TSH and FT_4 definitely indicates that R.K. is euthyroid, despite the confusing results of her other thyroid function tests. The depressed RAIU is consistent with her history of iodide ingestion and dilution of the ^{131}I. The low TT_4 and TT_3 may be explained by her cirrhosis and non-thyroidal illness syndrome (see Question 2). The negative thyroid antibodies, the normal scan, and normal DTRs further substantiate the diagnosis of euthyroidism. In hypothyroidism, a lower rate of cholesterol degradation can produce an elevated serum cholesterol level. However, because many extrathyroidal factors influence the serum concentration of cholesterol, this test is an imprecise reflection of thyroid status. In this case, the elevated cholesterol level is not related to hypothyroidism.

CASE 52-1, QUESTION 2: Assess the results and explain the significance of R.K.'s TT_4, FT_4I, and TT_3 values.

R.K.'s thyroid function test results are consistent with the non-thyroidal illness syndrome. Abnormal thyroid function tests are commonly found in euthyroid patients with various serious systemic diseases, including starvation, infections, sepsis, acute psychiatric disorders, HIV infection, myocardial infarction (MI), bone marrow transplantation, and severe chronic cardiac, pulmonary, renal, hepatic, and neoplastic diseases.[21,31,33,37–42]

This "euthyroid sick" syndrome occurs in 37% to 70% of chronically ill or hospitalized patients and must be recognized. In general, the sicker the patient, the greater the degree of abnormal thyroid function findings, even though the patient has no thyroid disease.

The most common finding is a low TT_3 (e.g., 15–20 ng/dL) and high inactive reverse T_3 levels (rT_3). Other typical changes include a normal or low TT_4, and a suppressed or normal TSH levels. A borderline-high compensatory TSH occurs as patients recover from illness. In more serious illness, the TT_4, FT_4I, and FT_3 are often low. Free hormone levels (e.g., FT_4, FT_3) are often normal or slightly low. However, these inconsistent findings fuel the controversy over whether thyroid hormone therapy is beneficial or detrimental. These findings are believed to be explained by a central hypothyroidism caused by reduction in hypothalamic TRH because of increased hypothalamic T_3, increased peripheral metabolism of T_3, or by a reduction in serum thyroid hormone–binding proteins.[38] Impaired protein synthesis of thyroid-binding prealbumin (TBPA) and an increase in the proportion of a lower-binding-capacity form of TBG might account for the lower bound hormone levels, but the concomitant increase in the free hormone concentrations would maintain a euthyroid state. Furthermore, circulating substances that inhibit the binding of T_4 and T_3 to the serum-binding proteins might also be present.

Less common changes include a modestly elevated TT_4 and FT_4I in patients with acute viral hepatitis, psychiatric disorders, renal failure, and advanced HIV infection. The TT_3 is usually normal but can be low in critically ill patients. Modest elevations in hormonal binding affinity and increased synthesis of TBG explain these findings.

Several studies have shown a strong inverse correlation between mortality and total serum T_4, T_3, and rT_3 levels.[39–41] Of the 86 hospitalized, intensive care patients, 84% of those with a serum T_4 of <3 mcg/dL died, whereas 85% of those with a serum T_4 of >5 mcg/dL survived.[40] In 331 patients with acute MI, rT_3 levels >0.41 nmol/L were significantly associated with a greater risk of death at 1 year.[41] During recovery, TSH levels increase and hormone levels start to normalize. Therefore, a favorable outcome is associated with reversal of the hormone indices.

Thyroid experts are divided about whether non-thyroidal illness should be treated, and few randomized studies are available to guide therapeutic decisions.[37–42] The few available studies found no survival benefits or favorable clinical outcomes from hormone therapy, although cardiac hemodynamics improved. The benefits of hormone replacement are unproven and might be detrimental. In one trial, the mortality of patients with acute renal failure treated with T_4 was 43% versus 13% in the control group.[42] Other small trials have shown thyroid hormones to be well tolerated and safe.[43] Opponents argue that T_4 therapy, by inhibiting TSH, may interfere with normal thyroid recovery and is preferentially converted to inactive rT3.[43,44] Conversely, proponents argue that there may be cardiovascular benefits and there is no clear evidence that therapy is toxic.[44]

In summary, T_4 and T_3 measurements are not helpful in the diagnosis of thyroid dysfunction in patients with significant non-thyroidal illness. A normal or near-normal TSH is necessary to establish euthyroidism in sick patients with non-thyroidal illness. The available data are not supportive of starting thyroid hormone treatment now. The abnormal laboratory findings should reverse with correction of R.K.'s non-thyroid illness. To confirm euthyroidism, the slightly elevated TSH should be repeated once R.K.'s medical condition improves.

Drug Interference with Thyroid Function Tests

CASE 52-2

QUESTION 1: J.R., a 45-year-old man, complains of fatigue, dry skin, and constipation. His other medical problems include alcoholism for 10 years, cirrhosis, generalized tonic–clonic seizures treated with phenytoin (Dilantin) 300 mg/day and phenobarbital 90 mg

---

at night, and rheumatoid arthritis for which he takes aspirin 325 mg, 12 tablets/day.

The results of his thyroid function tests are as follows:

TT_4, 4.2 mcg/dL (normal, 4.8–10.4)
FT_4, 0.6 ng/dL (normal, 0.8–1.4)
TSH, 2.5 microunits/mL (normal, 0.45–4.1)

How should these laboratory findings be interpreted? What factors are responsible for the observed changes?

Despite complaints that could be consistent with hypothyroidism (e.g., fatigue, dry skin, constipation) and findings of low serum hormone values, J.R. is euthyroid, as evidenced by the normal TSH level. Secondary hypothyroidism is unlikely at this age without a history of central nervous system (CNS) trauma or tumor. Some non-thyroidal factors could account for J.R.'s low TT_4 and FT_4 values.[21] Anti-inflammatory doses of salicylates >2 g/day and salicylate derivatives (i.e., Disalcid, salsalate) can displace T_4 from both TBG and TBPA, causing these abnormal findings.[21,45,46] Elevation in free T_4 levels and suppression of TSH below normal occur transiently (i.e., no longer than first 3 weeks of administration) but normalize with chronic administration. Cirrhosis, stress, severe infections, and hereditary factors can also decrease TBG and TBPA synthesis to produce similar TT_4 findings. A medication history for drugs such as androgens or glucocorticoids that can lower TBG levels, and therefore TT_4 levels, should be elicited (Table 52-1).[21]

Enzyme inducers, such as rifampin and anticonvulsants (phenytoin, phenobarbital, valproic acid, carbamazepine), can alter serum thyroid hormone levels.[21,47–52] A 40% to 60% reduction in total T_4 serum concentrations results from an increase in the metabolism (non-deiodination) of T_4 and from hormone displacement in patients receiving chronic anticonvulsant therapy. Serum T_3 levels are normal or slightly decreased. In addition, therapeutic levels of phenytoin and carbamazepine interfere with the FT_4 assay, causing a 20% to 40% lower FT_4 than would be expected in euthyroid persons.[48] TSH levels remain normal and patients are euthyroid; however, those who previously required T_4 therapy may need a dosage increase to maintain euthyroidism.[51,52] Valproic acid is reported to have similar but less potent effects on thyroid function.[47,49] Phenobarbital can increase T_4 uptake by the liver and increase the fecal excretion of T_4. Serum binding of thyroid hormones is unaffected by phenobarbital.

In summary, J.R. is taking several drugs that can further compromise the already low serum T_4 levels resulting from his liver disease. FT_4 remains subnormal in euthyroid persons receiving phenytoin. For J.R, the normal TSH confirms euthyroidism, and no thyroid replacement is warranted.

CASE 52-3

QUESTION 1: S.T., a 23-year-old, sexually active woman whose only medication is birth control pills, comes to the clinic complaining of extreme nervousness, diaphoresis, and scanty menstrual periods. Although she appears healthy, the possibility of hyperthyroidism is considered on the basis of the following laboratory values:

TT_4, 16 mcg/dL (normal, 4.8–10.4)
FT_4, 1.2 ng/dL (normal, 0.7–1.9)
TSH, 1.2 microunits/mL (normal, 0.45–4.1)

Based on this information, what would be a reasonable assessment of S.T.'s thyroid status?

The normal FT_4 and TSH confirm that S.T. is not hyperthyroid. The elevated TT_4 is consistent with increased TBG levels observed in patients with acute hepatitis; in pregnancy; and in persons taking estrogens, estrogen-containing contraceptives, tamoxifen, raloxifene, heroin, or methadone.[1,2,21,53–55] Because TBG and therefore bound T_4 levels are increased by estrogens in S.T., total serum T_4 measurements are falsely elevated, but free thyroxine levels remain normal. In patients requiring L-thyroxine, the use of estrogens can increase requirements of hormone replacement because the increased pituitary secretion of TSH cannot increase thyroid production needed to offset the increased binding of T_4.[1] Thyroid function tests should return to normal within 4 weeks after estrogen-containing contraceptives are discontinued. A change to progesterone-only contraceptives that do not affect protein binding, do not alter thyroid function tests, and do not increase thyroid requirements can be considered in S.T.

CASE 52-4

QUESTION 1: J.P., a 55-year-old woman, complains of 3 months of progressive tremors, dizziness, and ataxia. Two months ago, she had a silent MI complicated by malignant ventricular ectopy that was responsive only to amiodarone therapy. Her other medical problems include Parkinsonism, type 2 diabetes, and diabetic gastroparesis. Her current medications include amiodarone, insulin, metformin, metoclopramide, pramipexole, and levodopa/carbidopa. Physical examination of the thyroid was unremarkable. Thyroid function tests yielded the following results:

TT_4, 14.5 mcg/dL (normal, 4.8–10.4)
FT_4, 2.3 ng/dL (normal, 0.8–1.4)
TSH, 3.8 microunits/mL (normal, 0.45–4.1)
TT_3, 40 ng/dL (normal, 58–201)
TPOAb, 40 WHO units (normal, <100)

How should J.P.'s laboratory values be interpreted?

Although the symptoms of tremors, dizziness, and weight loss are suggestive of hyperthyroidism, the low TT_3, negative antibodies, normal TSH, and normal thyroid examination make this diagnosis unlikely. Side effects of amiodarone could be responsible for J.P.'s symptoms. Her drug therapy could also explain her laboratory findings.

Amiodarone produces complex changes in thyroid function tests that are confusing if not properly interpreted.[3,12,56,57] Because amiodarone inhibits both the peripheral and pituitary conversion of T_4 to T_3, FT_4 levels are elevated, and TT_3 levels are subnormal in euthyroid patients. Transient elevations in TSH levels occur (usually <20 microunits/mL) during the first few weeks of therapy but return to normal in approximately 3 months. If TSH levels do not normalize, then amiodarone-induced thyroid disease should be considered. Amiodarone can cause either hypothyroidism or hyperthyroidism in susceptible patients.

The other drugs J.P. is taking—pramipexole, levodopa, metformin, and metoclopramide—also add to the diagnostic confusion. Although these drugs do not affect the actual circulating hormone levels, they affect the dopaminergic system that controls both TSH and TRH secretion.[21,32,33,58] Infusions of dopamine and dobutamine can decrease both TSH secretion and the TSH response to TRH in euthyroid and hypothyroid patients.[21,32,33,59] Therefore, dopamine agonists such as pramipexole, cabergoline, and levodopa can blunt the normal TSH response.[21,32,58,59] In addition, metformin after 1 year of therapy can cause significant TSH suppression without changes in free thyroxine levels by as yet an unknown mechanism of action.[60,61] Conversely, dopamine antagonists such as metoclopramide or domperidone can elevate TSH levels.[21,32] Fortunately, the alterations in TSH caused by these agents are usually not substantial enough to completely obscure the true thyroid abnormality.

See Table 52-2 and Cases 52-23 and 52-24 for more information about drug effects on thyroid function.

J.P.'s thyroid tests present a confusing picture; however, the presence of a TSH within the normal range indicates euthyroidism. J.P. should be continued on her current regimen with follow-up monitoring of thyroid tests.

HYPOTHYROIDISM

Clinical Presentation

CASE 52-5

QUESTION 1: M.W., a 70-kg, 23-year-old voice student, thinks that her neck has become "fatter" over the past 3 to 4 months. She has gained 10 kg, feels mentally sluggish, tires easily, and finds that she can no longer hit high notes. Physical examination reveals puffy facies, yellowish skin, delayed DTRs, and a firm, enlarged thyroid gland. Laboratory data include the following results:

FT_4, 0.6 ng/dL (normal, 0.8–1.4)
TSH, 60 microunits/mL (normal, 0.45–4.1)
TPOAb, 136 WHO units (normal, <100)

Assess M.W.'s thyroid status based on her clinical and laboratory findings.

M.W. presents with many of the clinical features of hypothyroidism as presented in Table 52-3. These include weight gain, mental sluggishness, easy fatigability, lowering of the voice pitch, puffy facies, yellowish tint of the skin, delayed DTRs, and enlarged thyroid.[62] The diagnosis of hypothyroidism is confirmed by her laboratory findings of a low FT_4, an elevated TSH value, and positive TPOAb.

A firm goiter, thyroid antibodies, and clinical symptoms of hypothyroidism strongly suggest Hashimoto's thyroiditis. She has no history of prior antithyroid drug use, surgery, or RAI treatment, which are common causes of iatrogenic hypothyroidism. She is also not taking any goitrogens or drugs known to cause hypothyroidism (Table 52-2).

Treatment with Thyroid Hormones

THYROID HORMONE PRODUCTS

CASE 52-5, QUESTION 2: What thyroid preparation should be used to treat M.W.'s hypothyroidism? Are differences, advantages, or disadvantages significant among the various generic and brand name formulations of thyroid hormones?

The principal goals of thyroid hormone therapy are to attain and maintain a euthyroid state. Thyroid preparations (Table 52-8[63–66]) are synthetic (L-thyroxine, L-triiodothyronine, liotrix) or natural (desiccated thyroid). The latter come from animal tissues.

Desiccated Thyroid

Desiccated thyroid is derived from pork thyroid glands, although beef and sheep are also used. Today, starting patients on desiccated thyroid is not justified. The USP requires only that desiccated thyroid contain 0.17% to 0.23% organic iodine by weight. These requirements do not seem stringent enough because potency may vary with changes in the proportion of the two active hormones (T_3 and T_4) or with changes in the amount of organic iodine present.[67,68] This variable potency seems to be particularly true of generic formulations compared with the biologically standardized Armour brand of desiccated thyroid. Inactive desiccated thyroid preparations that contain negligible amounts of T_3 and T_4 or even iodinated casein instead of active hormone have been identified in various brands sold in retail pharmacies and in over-the-counter products found in health food stores.[68–70] Likewise, preparations with greater-than-expected activity caused by an abnormally high T_3 content have resulted in thyrotoxicosis.

Table 52-8

Thyroid Preparations

Drug/Dosage Forms	Composition	Dosage Equivalent	Comments
Thyroid USP (Armour) Tab: 0.25, 0.5, 1, 1.5, 2, 3, 4, and 5 gr	Desiccated hog, beef, or sheep thyroid gland Standardized iodine content	1–1.67 gr[a]	Unpredictable T_4:T_3 ratio; supraphysiologic elevations in T_3 levels might produce toxic symptoms; Armour brand preferred
L-Thyroxine (Levoxyl, Levothroid, Synthroid, Unithroid, various) Tab: 0.013, 0.025, 0.050, 0.075, 0.088, 0.112, 0.125, 0.137, 0.15, 0.175, 0.2, and 0.3 mg Inj: 200 and 500 mcg	Synthetic T_4	60 mcg[a]	Stable, predictable potency; well absorbed; more potent than desiccated thyroid. When changing from >2 gr desiccated thyroid to L-T_4, a lower dosage of L-T_4 might be needed to avoid toxicity. Weight should be considered in dosing (1.6–1.7 mcg/kg/day). L-T_4 absorption can be impaired by iron, aluminum-containing products (e.g., antacids, sucralfate), Kayexalate, calcium preparations, proton pump inhibitors, cholesterol resin and phosphate binders, raloxifene, soy, bran, coffee,

			fiber enriched foods. L-T_4 metabolism increased by anticonvulsants, rifampin, imatinib, bexarotene, and pregnancy
L-Triiodothyronine (Cytomel) Tab: 5, 25, and 50 mcg Inj: 10 mcg/mL (Triostat)	Synthetic T_3	25–37.5 mcg	Complete absorption; requires multiple daily dosing; toxicity similar to all T_3-containing products; see desiccated thyroid comments
Liotrix (Thyrolar) Tab: 0.25, 0.5, 1, 2, and 3 gr	60 mcg T_4:15 mcg T_3 50 mcg T_4:12.5 mcg T_3	Thyrolar-1	No need for liotrix because T_4 is converted to T_3 peripherally; expensive, stable, and predictable content

[a]Historically, 60 mg (1 gr) of desiccated thyroid = 60 mcg of T_4.[66] This conversion was determined with older TSH assays, without direct measurement of FT_4 and has been challenged. The conversion is now typically reported as 80 mcg[63], 88 mcg,[64] or 100 mcg[65] of T_4 per 60 mg of desiccated thyroid. The T_3 component of desiccated thyroid is an additional factor to consider when converting from one to the other and an exact equivalent dose has not been determined.

gr, grain; Inj, injection; L-T_4, levothyroxine; T_3, triiodothyronine; T_4, thyroxine; Tab, tablet; USP, United States Pharmacopeia.

Allergic reactions to the animal protein are another concern. In addition, desiccated thyroid suffers from two problems inherent to all T_3-containing preparations. Because T_3 is absorbed more rapidly than T_4, supraphysiologic elevations in plasma T_3 levels occur after oral ingestion, which can produce mild thyrotoxic symptoms in some patients. FT_4 levels are low during T_3 administration and, if misinterpreted, can result in the erroneous administration of more hormone. These problems with T_3 are easily missed unless T_3 levels are routinely monitored. Because significant amounts of T_4 are converted to T_3 peripherally, oral administration of T_3 offers no advantage and is not usually needed (see Triiodothyronine section).

Loss of tablet potency can occur from prolonged storage of desiccated thyroid preparations, but this instability is not as important as once believed. Because the only apparent advantage of desiccated thyroid is its low cost, it should not be considered the drug of choice for replacement therapy. Patients maintained on desiccated thyroid should be encouraged to change to L-thyroxine (T_4). Although 60 mg (1 g) of desiccated thyroid is theoretically equal in potency to 75 to 100 mcg of T_4,[66] this equivalency may not hold true if the desiccated thyroid preparation is less active than its labeled content. The patient's weight should also be considered when switching therapy (see Case 52-5, Question 3).

The synthetic thyroid preparations differ from one another in their relative potency, onset of action, and biological half-life.

Levothyroxine or L-Thyroxine

L-Thyroxine is the thyroid replacement of choice.[35,65,71] Its advantages include stability, uniform potency, relatively low cost, and lack of allergenic foreign protein content. The long half-life of 7 days permits once-a-day dosing and, if necessary, the creation of special convenience schedules, such as the omission of medication on weekends. The mean absorption of a commonly used branded preparation is 81%.[72] Absorption is optimal on an empty stomach.[73] Current guidelines recommend taking L-thyroxine either 60 minutes before breakfast or 3 to 4 hours after the evening meal for consistent absorption.[35,65] Several medications can also impair L-thyroxine absorption (see Case 52-9, Question 1).

Concerns about generic and branded L-thyroxine tablet stability and potency, bioavailability, and product interchangeability existed because L-thyroxine preparations were grandfathered in by the 1938 Food, Drug, and Cosmetic Act. To address these concerns, the U.S. Food and Drug Administration (FDA) required that all manufacturers of L-thyroxine products submit a New Drug Application (NDA) by August 2001 or cease production by 2003 if the NDA was not filed.[74] Several FDA-approved brand and generic (formulations approved under the NDA received AB or BX ratings, indicating interchangeability for some generic and brand preparations. Raising concerns about the methodology the FDA used to determine bioequivalence, the American Thyroid Association, The Endocrine Society, and the American Association of Clinical Endocrinologists issued joint position statements expressing their displeasure with the FDA's conclusions of interchangeability.[75] Abbot Laboratories, the manufacturer of Synthroid, and others also disagreed with the FDA's findings.[76] Although this issue remains controversial, the preponderance of the evidence supports the FDA ratings and suggests that these preparations are likely to be interchangeable in the majority of patients.[35,65,77–80]

Triiodothyronine

T_3 (Cytomel) is not recommended for routine thyroid hormone replacement because of the problems identified earlier with T_3 administration (see Desiccated Thyroid section).[71] Numerous randomized studies now conclude that replacement with combination T_4 and small dosages of T_3 offer no advantage to T_4 alone, despite an initial study showing improved cognitive performance and mood changes[81,82] Furthermore, a prospective study found that T_3 levels post-thyroidectomy in 50 patients receiving only levothyroxine were similar to T_3 levels in these euthyroid patients before surgery confirming that levothyroxine alone is sufficient for replacement.[83] Its use to enhance contractility in coronary bypass surgery is controversial.[84]

Although T_3 is well absorbed, it has a relatively short half-life (1.5 days), necessitating multiple daily dosing to ensure a uniform response. Other disadvantages include higher expense and a greater potential for cardiotoxicity. Its primary use is for patients who require short-term hormone replacement therapy and rarely in those in whom T_4 conversion to T_3 might be impaired. Proponents favoring thyroid treatment of the "euthyroid sick" syndrome identify T_3 as the hormone replacement of choice. T_3 therapy should be monitored using the TSH and TT_3 or FT_3 levels.

Liotrix

Liotrix is a combination of synthetic T_4 and T_3 in a physiologic ratio of 4:1. This preparation is subject to the same disadvantages common to all T_3-containing preparations. It is also stable and potent, but it is more expensive than other thyroid preparations. Because oral administration of T_3 is not needed and there is no advantage of adding T_3 to T_4 therapy, this expensive preparation is not recommended.[81,82] Patients should be changed to an equivalent dosage of L-thyroxine.

THYROXINE

Dosage

CASE 52-5, QUESTION 3: What would you recommend as appropriate starting and maintenance dosages of T_4 for M.W.?

The maintenance dosage for M.W. can be estimated from her weight. Average replacement doses of 1.6 to 1.7 mcg/kg/day (e.g., 100–125 mcg) are sufficient in most patients to normalize the TSH.[62,71] L-Thyroxine dosages that suppress TSH levels to below normal or undetectable levels (subclinical hyperthyroidism) should be avoided to prevent osteoporosis and cardiac toxicity.[71,85–89] Excessive L-thyroxine can cause tachycardia, atrial arrhythmias, impaired ventricular relaxation, reduced exercise performance, and increased risk of cardiac mortality.[85] These considerations are especially important in older patients, who might require less T_4 than their younger counterparts and who are particularly sensitive to minute changes in T_4 doses (see Case 52-6). As patients age, the dosage should be evaluated yearly and decreased if necessary to maintain a normal TSH level.

How rapidly T_4 replacement can proceed depends on the likelihood of invoking cardiac toxicity in susceptible patients. Minute doses of T_4 (e.g., <75 mcg) can increase heart rate, stroke volume, oxygen consumption, and cardiac workload before euthyroidism occurs. One double-blind study compared the clinical outcome between starting full replacement doses versus gradual 25-mcg incremental doses in relatively young hypothyroid subjects with asymptomatic cardiac disease and concluded that those receiving full doses normalized thyroid function tests more rapidly (4 weeks) and without any toxicity.[90] Because M.W. has no identifiable risk factors (see Case

52-11, Question 3) for cardiotoxicity that require careful dosage titration (e.g., old age, cardiac disease, long duration of hypothyroidism), she can be started on an estimated full

---

replacement dose of 125 mcg daily of L-thyroxine (70 kg × 1.7 mcg/kg/day = 120 mcg).[35] An alternative conservative approach would be to start with 100 or 112 mcg/day, check the FT_4 or FT_4I and TSH tests after 6 to 8 weeks of therapy, and if the TSH is still elevated without any symptoms of toxicity, increase the dosage to 125 mcg/day. The appropriate replacement dose will produce a TSH of 1 to 2 microunits/mL, normalize FT_4 or FT_4I levels, and reverse clinical symptoms of hypothyroidism. Generally, dosing adjustments should not exceed monthly increments of 12.5 to 25 mcg/day. Even in the absence of overt coronary disease, patients over age 50 to 60 should be started on a lower dose of L-thyroxine (50 mcg/day) and titrated.[35]

Monitoring Therapy

CASE 52-5, QUESTION 4: Ten days after starting L-thyroxine therapy, M.W. continues to complain of tiredness, fatigue, and difficulty singing despite excellent adherence. Thyroid function tests show a TT_4 of 4 mcg/dL (normal, 4.8–10.4), an FT_4 of 0.5 ng/dL (normal, 0.8–1.4), and a TSH of 40 microunits/mL (normal, 0.45–4.1). What therapeutic options are available? How should M.W.'s thyroid function tests be interpreted?

Clinical improvement in the signs and symptoms of hypothyroidism and normalization of laboratory parameters are appropriate therapeutic end points. If the replacement dose is sufficient, some correction of her symptoms should occur after 2 to 3 weeks, but maximal effects will not be evident for 4 to 6 weeks. Typically, improvement of anemia and hair and skin changes is delayed and requires several months of treatment before resolution.[60,66]

In patients with severe myxedema, a transiently elevated T_4 level might occur at 6 weeks because the metabolic clearance of T_4 is decreased by the hypometabolic state associated with hypothyroidism.

FT_4 or FT_4I and TSH should be checked about 6 to 8 weeks after the initiation of therapy because T_4 has a half-life of 7 days, and three to four half-lives are needed to reach steady-state levels. Levels obtained before this time (as in M.W.) may be misleading and should be interpreted cautiously. No change in her L-thyroxine dosage should be attempted at this time.

CASE 52-5, QUESTION 5: Eight weeks later, on a routine follow-up visit, M.W. still feels tired and not back to her normal self. She denies any symptoms of hyperthyroidism. Her thyroid function tests show a TT_4 of 14 mcg/dL (normal, 4.8–10.4), a TT_3 of 100 ng/dL (normal, 58–201), FT_4 of 1.9 ng/dL (normal, 0.7–1.9), and a

TSH of 3.5 microunits/mL (normal, 0.45–4.1). How should M.W.'s thyroid function tests be interpreted? What changes, if any, should be recommended in her therapeutic regimen?

Patients treated with L-thyroxine may develop an elevated TT_4 concentration and FT_4 without overt clinical signs of hyperthyroidism.[83,91] Despite these elevated levels, patients are euthyroid, as evidenced by a normal TSH. Because T_3 is not being released from the nonfunctioning thyroid gland, a higher concentration of T_4 is necessary to increase the amount of T_3 obtained from peripheral conversion. Jonklaas et al. reported that the mean FT_4 was significantly higher (1.34 ng/dL) in patients receiving L-thyroxine postoperatively compared to their euthyroid levels before thyroidectomy (FT_4, 1.06 ng/dL).[83] T_3 levels on L-thyroxine replacement were also comparable after surgery to presurgery levels. However, lower T_3 levels were noted only in those in whom TSH levels were greater than 4.5 microunits/mL, indicating that low T_3 levels are likely a result of suboptimal L-thyroxine replacement. Thus, the TSH appears to be the best indicator of euthyroidism in patients treated with L-thyroxine.

Another possibility is that the elevated thyroid levels may only be an artifact of the laboratory collection time. Before any changes in her dosing regimen are made, M.W. should be asked about the time she takes the drug and its relationship to the time of her blood draw. Random sampling of FT_4 and TSH levels can be significantly different when compared with trough levels.[92,93] In one study, the FT_4 level was 12% higher and the TSH level 19% lower when obtained from random samples compared with trough samples.[93] Transient elevations in FT_4 levels were detected for 9 hours after ingestion of the oral L-thyroxine.

The symptoms of fatigue that M.W. is experiencing are likely not because of her hypothyroidism. Patients may continue to have symptoms of hypothyroidism despite normalization of the TSH value. Although some have suggested that the goal TSH be titrated to 1 to 2 microunits/mL or lower for replacement therapy to improve well-being, this is controversial. One study found that changes in T_4 dosing to achieve TSH concentrations of 2 to 4.8 microunits/mL, 0.3 to 1.9 microunits/mL, or <0.3 microunits/mL in hypothyroid patients did not result in improvements in well-being, psychologic, or hypothyroid symptoms, or quality of life.[94] Data justifying the safety of higher T4 replacement doses found that achievement of a low but detectable TSH level (0.04–0.4 microunits/mL) was not associated with an increased risk of cardiovascular disease or fractures compared to those with suppressed (<0.03 microunits/mL) or elevated (>4 microunits/mL) TSH levels.[95]

In conclusion, if an elevated TT_4 and FT_4 are noted without any symptoms of thyrotoxicosis (as in M.W.), the dosage should not be decreased; rather, a trough FT_4 and TSH level should be obtained to eliminate excessive dosing or any laboratory artifacts. Alternatively, obtaining a level at least 9 hours after levothyroxine administration also seems appropriate. Repeat values should be in the normal range if the dosing is correct. An excessively suppressed TSH confirms a dosage that is too high. In M.W., the lack of hyperthyroid symptoms suggests euthyroidism, and no changes in her therapeutic regimen should be attempted until trough levels are available. Evaluation for other causes of fatigue should be explored.

TRIIODOTHYRONINE

CASE 52-6

QUESTION 1: C.B., a 65-year-old woman, complains of fatigue and vague muscle aches and pains, which she attributes to insufficient thyroid medication. On physical examination, the thyroid gland is palpable but not enlarged, and DTRs are 2 plus and brisk. Her dose of T_3 was increased from 25 mcg TID to 50 mcg TID about 2 weeks ago based on the results of a recent FT_4 of 0.5 ng/dL (normal, 0.8–1.4). She denies taking any other medications. Is C.B.'s thyroid hormone replacement appropriate?

As noted previously, T_3 is not the drug of choice for thyroid replacement. The use of L-thyroxine would simplify her dosing regimen and facilitate monitoring.

The low FT_4 did not justify increasing C.B.'s T_3 dose. Because she is receiving T_3, the FT_4, which is a measure of free T_4, will always be low and will never reach normal levels. In fact, her vague complaints may be related to hyperthyroidism because she is receiving the equivalent of 0.2 to 0.3 mg of L-thyroxine daily. TSH and FT_3 levels are most useful in monitoring patients receiving T_3 therapy. A TSH level should be obtained to evaluate her thyroid function. A suppressed TSH and an elevated FT_3 would indicate hyperthyroidism. It is important to remember that in an older patient, hyperthyroidism might not always produce symptoms because of an "apathetic" sympathetic system.

L-Thyroxine should be initiated cautiously in older patients to avoid exacerbating any preexisting arteriosclerotic heart disease that might be masked by the hypothyroidism (see Case 52-11, Questions 2 and 3). In general, older patients require smaller replacement dosages (approximately $\leq$1.6 mcg/kg/day of T_4) than their younger counterparts.[96–98] Dosages of <50 mcg/day of T_4 are common in patients older than 60 years. However, this lower T_4 dosage is not universal for all older subjects.[98] The reason that older patients need lower dosages is unclear, but it has been suggested that the lower requirements result from an age-related decrease in T_4 degradation rates. Because dosage requirements change with age, patients should be reassessed annually to determine whether the original dosage prescribed is still appropriate.

In C.B., who had been on T_3 without any evidence of cardiac toxicity, a less cautious approach in changing to T_4 can be attempted. An empiric L-thyroxine dosage of 68 mcg/day (40 kg × 1.6 mcg/kg/day) is an approximate dosing end point for C.B. The T_3 should be discontinued and T_4 initiated in a dose of 50 mcg/day; this dosage can be adjusted as needed based on C.B.'s symptoms and thyroid function tests. After T_3 therapy is discontinued, its effects will disappear over 3 to 5 days. In contrast, T_4 levels rise slowly over 4 to 5 days, so no overlap in T_3 administration is necessary to prevent hypothyroidism.

Parenteral Dosing

CASE 52-7

QUESTION 1: G.F., a 70-year-old man with long-standing hypothyroidism, has been receiving L-thyroxine 0.1 mg/day. Currently, he is in the hospital with a stroke and paralysis that prohibits him from swallowing oral medications. His last thyroid function tests were normal. What is a reasonable method of administering thyroid hormone to G.F.?

Because L-thyroxine has a half-life of 7 days, administration can be delayed for up to 1 week, assuming G.F. can resume oral intake at that time. However, if parenteral administration is required, L-thyroxine is available as an intramuscular (IM) or IV injection. The IV route is preferred because IM absorption may be slow and unpredictable, particularly if the circulation is compromised. Because the oral absorption of T_4 is approximately 80%,[72] parenteral doses should be decreased. Once IV L-thyroxine replacement is successful, maintenance with a once-weekly IM injection can be continued if oral ingestion is not feasible.[99]

Hypothyroidism in Pregnancy

CASE 52-8

QUESTION 1: P.K. is a 35-year-old woman with Hashimoto's thyroiditis, who is 6 weeks pregnant. Laboratory test results showed TT_4, 5 mcg/dL (normal, 4.8–10.4) and FT_4, 0.7 ng/dL (normal, 0.8–1.4). She takes her medications in the morning, which include L-thyroxine 0.1 mg/day and a prenatal vitamin enriched with iron and calcium. What dosing adjustments are required because of P.K.'s pregnancy?

Inadequately treated or undiagnosed maternal hypothyroidism can be detrimental to the mother and the developing fetus.[100,101] Miscarriage, spontaneous abortion, hypertension, preeclampsia, and higher rates of cesarean sections and stillbirths have been reported with maternal hypothyroidism. Congenital defects, congenital hypothyroidism (see Case 52-8, Question 2), abnormal fetal development, and impaired cognitive development in the newborn have been attributed to maternal hypothyroidism. The IQ scores of children born to mothers with undiagnosed hypothyroidism during pregnancy averaged 7 points lower than children born to euthyroid mothers.[100] A delay in both mental and motor development was observed in children aged 1 to 2 years old who were born to mothers with hypothyroxinemia but normal TSH levels during the first trimester of pregnancy.[101] Normal maternal thyroid function is essential during early fetal development. Fetal thyroid hormone production begins by the end of the first trimester, with the fetus relying on maternal thyroid hormones until that time. Transfer of maternal thyroid hormones is under the control of the placenta.[102] The risk of congenital hypothyroidism is small if maternal antibodies from Hashimoto's thyroiditis cross the fetal circulation. The infant's cord blood should be assayed at birth to ensure that TSH is normal and that the child is euthyroid.

The majority of women with primary hypothyroidism will require a 30% to 50% increase in the prepregnancy T_4 dosage to maintain euthyroidism during the first trimester of pregnancy.[102–105] The only evidence of increased T_4 demands is an elevated TSH level (e.g., subclinical hypothyroidism) that occurs between weeks 5 (but can be as early as 3) and 16 of gestation. Often, no clinical symptoms of hypothyroidism are evident, and the FT_4 and the index are normal. Because of the adverse consequences associated with maternal hypothyroidism, some have advocated universal TSH screening of all pregnant women[106] as well as empirically increasing the prepregnancy T_4 dosage by 30% (extra 2 pills/week) as soon as pregnancy is confirmed.[104] Because there is a physiologic decrease in TSH during pregnancy caused by the TSH-like activity of human chorionic gonadotropin, the upper limit of the normal TSH range should be adjusted for pregnancy.[102] TSH should be no higher than 2.5 microunits/mL during the first trimester and 3.0 microunits/mL in the second and third trimesters.[105]

Physiologic explanations for the increase in thyroid hormone requirements include the twofold increase in TBPA caused by high estrogen levels, increased volume of distribution of thyroid hormones, as well as maternal transport of T_4.[102,105] Rising HCG concentrations result in increased production of thyroid hormones.[102] Changes in serum proteins cause direct immunoassay of FT_4 to yield incorrect results. A newer assay, measurement of T_4 in the dialysate or ultrafiltrate of serum samples using liquid chromatography or tandem mass spectrometry, has been shown to produce reliable trimester-specific reference ranges for FT_4; however, these assays are not universally available.[107] In the absence of trimester-specific reference ranges for dialysate or ultrafiltrate measured FT_4, the FT_4 index or TT_4 should be used to evaluate thyroxine production.[35] It is important to recognize that coadministration of iron- and calcium-containing prenatal vitamins reduced T_4 absorption (see Case 52-9, Question 1) and that these drug interactions may affect dosage requirements. When prenatal vitamins with iron and calcium were separated by 4 hours from T_4 administration, only 31% of women required an increase in T_4 dose.[108] The increase in thyroid hormone requirements are likely because of a combination of physiologic and drug interaction causes. Women should be followed closely during pregnancy with monthly monitoring during the first half of pregnancy and at least once between gestation weeks 26 and 32. If necessary, the T_4 dosage should be adjusted to maintain a TSH in pregnancy-adjusted ranges and an ultrafiltrate-measured FT_4, FT_4I, or TT_4 in the upper limits of normal based on adjusted normal ranges. When the TT_4 is used, reference ranges should be increased by 50%.[35,107]

P.K.'s low TT_4 and FT_4 are concerning. The TT_4 should be much higher because of pregnancy-associated increases in TBG. The TSH level should be obtained, and the daily dosage of T_4 should be increased to 125 mcg after eliminating the possibility of patient non-adherence and drug interactions. Ingestion of the prenatal vitamins with iron and calcium should be separated by at least 4 hours from T_4. PK could also be instructed to take the T_4 at night for better absorption.[73] The TSH should be repeated in 6 weeks, and the dosage should be adjusted as needed to keep the TSH in the range as above. After delivery, the dosage should be reduced to prepregnancy levels and the FT_4 and TSH rechecked to ensure euthyroidism.

CONGENITAL HYPOTHYROIDISM

CASE 52-8, QUESTION 2: P.K. delivered a healthy baby, T.K., at term without difficulty. T.K.'s postpartum screening serum T_4 level was 5 mcg/dL (normal, 4.8–10.4), and TSH was 35 microunits/mL (normal, 0.45–4.1). At home, T.K. became lethargic, had a weak cry, sucked poorly, and failed to thrive. Assess the situation (including a treatment plan and prognosis). How is mental development affected?

T.K.'s symptoms are suggestive of congenital hypothyroidism, although in most infants the clinical signs and symptoms are so subtle and nonspecific that they are easily missed until the child is several months old. The early clinical findings include prolonged jaundice, skin mottling (cutis marmorata), lethargy, poor feeding, constipation, hypothermia, hoarse cry, large fontanels, distended abdomen, hypotonia, slow reflexes, and piglike facies. Respiratory difficulties, delayed skeletal maturation, and choking (but not palpable goiter) may be present. These infants are also at risk for additional congenital defects or complications.[109] Mass neonatal screening programs have been successful in detecting congenital hypothyroidism within the first few weeks of life before clinical manifestations are apparent and before irreversible changes occur.

The postpartum low serum T_4 concentration and elevated TSH level (>20 microunits/mL) in T.K. are of concern and should be verified. Transient hypothyroidism can result from intrauterine exposure to thioamides or excess iodides, or from transplacental passage of TRAb from the mother. Thyroid function tests often normalize without treatment in 3 to 6 months as the TRAb is cleared by the infant.[109] The diagnosis of hypothyroidism should be confirmed by a low serum T_4, a low FT_4, and an elevated TSH concentration during the next few weeks. Serum T_3 concentrations are often in the normal range and are not helpful. Normal serum T_4 concentrations are higher in the first few weeks of life and gradually return to normal by 2 to 4 months of life. The FT_4I may also be elevated. Because of these confusing changes, thyroid serum levels should be compared with the normal range for the approximate postnatal age.

Thyroid hormones play a critical role in normal growth and development, particularly of the CNS, during the first 3 years of life. If untreated, dwarfism and irreversible mental retardation occur. T.K.'s normal mental (IQ) and physical development will be determined by the age at which treatment is started, the initial dosage of T_4, the serum T_4 level attained during therapy, the adequacy with which treatment is maintained, and the cause and severity of the initial deficiency.[110–116] There is an inverse relationship between the amount of time to reach a euthyroid state and the likelihood of impaired neurologic development.[109]

Sodium L-thyroxine is the preparation of choice for replacement. T_4 tablets can be crushed and mixed with breast milk or formula; suspensions are not stable and should not be used. T_4 tablets should not be mixed with soy-based formulas because decreased absorption and longer time to reach a TSH <10 microunits/mL may occur. If a soy-based formula is required, the dosage of T_4 should be administered halfway between feeds.[109] T_3 is less desirable because its short half-life causes a greater fluctuation in plasma levels (Table 52-8). The initial replacement dose of T_4 should raise the serum T_4 as rapidly as possible to minimize the consequences of hypothyroidism on cognitive function. A delay in starting therapy of even a few days has resulted in a poorer IQ outcome.[111,112,116] A minimum T_4 dosage of 10 to 15 mcg/kg/day is recommended to raise the serum T_4 to >10 mcg/dL (129 nmol/L) by 7 days.[110] However, some suggest that higher than previously recommended dosages of 12 to 17 mcg/kg/day might be more effective, but concern about negative neurologic outcomes exists.[109,111,112] In the full-term healthy infant, full initial replacement T_4 doses are appropriate unless the infant has underlying heart disease or is extremely sensitive to the effects of thyroid hormones. In these infants, reduced doses of T_4 (approximately 25%–33% of the recommended dose) can be started and increased gradually by similar increments until the therapeutic dose is achieved. The recommended replacement dose decreases with age and is shown in Tables 52-4 and 52-9.

Table 52-9

T_4 Recommended Replacement Dose

Age	Daily mcg/kg T_4
3–6 months	10–15
6–12 months	5–7
1–10 years	3–6
>10 years	2–4

T_4, thyroxine.

Mental development and attainment of normal growth are not severely impaired if adequate T_4 treatment is initiated before 3 months of age to achieve a T_4 level >10 mcg/dL (129 nmol/L).[109–112,114] Children with the most severe congenital hypothyroidism had IQs lower than their siblings.[113] Young adults 20 years after congenital hypothyroidism showed impaired motor and intellectual outcomes after suboptimal T_4 (<7.8 mcg/kg/day) therapy compared to sibling controls.[114] However, those receiving optimal therapy still had some memory, attention, and behavior deficits.[117] Newborns starting L-thyroxine during the first 4 to 6 weeks of life have mean IQs similar to controls. The IQ drops if treatment is delayed until 6 weeks and 3 months (mean IQ, 95), or until 3 and 6 months (mean IQ, 75). When treatment is delayed until 6 months to 1 year of age, normal mental development is impaired despite subsequent treatment. Higher IQs also were found in children who received T_4 dosages >10 mcg/kg/day and achieved a mean T_4 level >14 mcg/dL (181 nmol/L) in the first month of therapy.[109,111,112,116,118] Neurologic deficits were also more likely to occur in infants whose thyroid replacement was delayed or inadequate (T_4 <8 mcg/dL [103 nmol/L] within 30 days of therapy and/or had delayed TSH normalization [18–24 months]). Additional risk factors for low IQs and poor motor and speech skills despite adequate therapy include clinical signs of hypothyroidism during fetal life, T_4 <2 mcg/dL at birth, thyroid aplasia, and retarded bone age.[109,110,112]

The goal of therapy is a T_4 in the upper normal range (e.g., 10–18 mcg/dL and/or an FT_4 of 2 to 5 ng/dL) during the first 2 weeks of therapy, and then a lower target thereafter: a T_4 of 10 to 16 mcg/dL (and/or an FT_4 of 1.6–2.2 ng/dL). IQs are improved if TSH levels are normalized within the first month of therapy but no later than 3 months.[111,112,116,118] Thyroid function tests should be routinely monitored 2 to 4 weeks after starting therapy, then every 1 to 2 months during the first 6 months of life, every 3 to 4 months until age 3, and finally, every 6 to 12 months until growth is complete.[109] Although TSH suppression is the most reliable index of adequate replacement in older children, normalization of the TSH should not be used as the sole monitoring parameter in infants because the TSH may lag behind correction of the T_4 and/or FT_4 levels. Overtreatment should be avoided to prevent brain dysfunction, acceleration of bone age, and craniosynostosis (premature closure of the cranial sutures). Normal growth and development should also be a treatment goal. Other clinical end points include an improvement in activity level, skin color, temperature, facial appearance, and reversal of other symptoms and signs of hypothyroidism. The child will require lifelong replacement therapy.

UNRESPONSIVENESS TO LEVOTHYROXINE AND DRUG–DRUG INTERACTIONS

CASE 52-9

QUESTION 1: R.T., a 45-year-old woman, complains of weight gain, heavy menses, sluggishness, and cold intolerance. Her present medical problems include Hashimoto's thyroiditis, treated with L-thyroxine 150 mcg daily; hypercholesterolemia treated with cholestyramine 4 g 4 times a day (QID); anemia, treated with $FeSO_4$ 325 mg twice a day (BID); dysmenorrhea treated with estrogen-containing birth control pills daily; and a history of peptic ulcer disease, treated with antacids and sucralfate 1 g BID. She was recently started on calcium carbonate 1 g BID and raloxifene 60 mg daily to protect her bones. Her laboratory data include the following findings:

Cholesterol serum concentration, 280 mg/dL
TSH, 21 microunits/mL (normal, 0.45–4.1)
FT_4, 0.6 ng/dL (normal, 0.8–1.4)
Positive TgAb and TPOAb

R.T. admits that she self-increased her L-thyroxine dose because she feels better on the higher dose. Why is R.T. apparently unresponsive to thyroid therapy?

R.T.'s complaints and laboratory values confirm inadequate treatment of hypothyroidism despite thyroid therapy. Possible causes of therapeutic failure include non-adherence, error in diagnosis, poor absorption, subpotent medication, rapid metabolism, and tissue resistance.[71,119,120] Thyroid resistance is rare, and non-adherence, error in diagnosis, and rapid metabolism do not appear to be reasonable explanations in R.T.

The most likely explanations are poor bioavailability and/or a subpotent preparation. The timing of T_4 administration with her meals should be ascertained because its bioavailability is improved when it is taken on an empty stomach and at night.[71,73,121,122] Significantly lower TSH levels are achieved when levothyroxine is taken on an empty stomach than with food or at night.[122] Simultaneous coadministration of T_4 with soy proteins, coffee, or high-fiber diets (e.g., oat bran, soybean) should also be avoided because T_4s absorption can be impaired.[123–125] R.T.'s history does not include surgical bowel resection or GI disorders (e.g., steatorrhea, malabsorption). Evidence for incomplete absorption of the hormone can be obtained by comparing R.T.'s response to oral and parenteral T_4.[119]

L-Thyroxine bioavailability can also be compromised by the numerous medications that R.T. is taking. Estrogen therapy can increase T_4 requirements by increasing TBG to increase T_4 binding.[1] Cholestyramine, colestipol, iron sulfate, antacids, sucralfate, calcium preparations, particularly the carbonate salt, and raloxifene can impair thyroid absorption if these medications are administered at the same time.[71,126–133] Cholesterol-lowering agents (e.g., lovastatin) and phosphate binders are also reported to interfere with thyroid absorption.[129,134] R.T. should be questioned about the time she takes her thyroid medication. She should be instructed to take it on an empty stomach or at night,[73] and at least 12 hours apart from the raloxifene and 4 hours apart from the iron, calcium, and cholestyramine.[126–133] Aluminum-containing products (i.e., antacids, sucralfate) should be discontinued because separating the concurrent administration of T_4 and her aluminum-containing preparations does not consistently correct this interaction.[130,131] R.T. should be changed to an aluminum- and calcium-free antacid and, if necessary, an H_2-receptor antagonist. Proton pump inhibitors (e.g., omeprazole) should be avoided because decreased acid secretion may reduce T_4 absorption, although data are conflicting.[135,136] After R.T. has been instructed on the proper times of administration for her medications, the therapeutic response and thyroid function tests should be reevaluated in 6 to 8 weeks before any changes are made.

CASE 52-9, QUESTION 2: Could R.T.'s hypothyroidism be responsible for her hypercholesterolemia?

Type IIa hypercholesterolemia is the most common lipid abnormality observed in patients with primary hypothyroidism.[137] Although the rate of cholesterol synthesis is normal in hypothyroid patients, the rate of cholesterol clearance is decreased. Similarly, slow removal of triglycerides may result in hypertriglyceridemia. Hypercholesterolemia is frequently observed before the appearance of clinical hypothyroidism. Treatment with T_4 alone should lower the cholesterol levels if no other causes are contributing.

Myxedema Coma

CLINICAL PRESENTATION

CASE 52-10

QUESTION 1: R.B., a 65-year-old, agitated woman arrived at the emergency department complaining of chest pain unrelieved by nitroglycerin (NTG). Her medical problems include alcoholic cardiomyopathy, angina, and hypothyroidism. Although she has been advised repeatedly to take her T_4 regularly, she continues to take it sporadically. A FT_4 drawn 4 months ago was 0.5 ng/dL (normal, 0.7–1.9). Haloperidol 2 mg IM and morphine sulfate 10 mg IM were given for the agitation. After the injection, the nurse noticed mental depression, lethargy, and shallow breathing. R.B.'s oral temperature was 34.5°C, and she exhibited chills and shakes. What is your assessment of R.B.'s subjective and objective data?

R.B. has several symptoms consistent with myxedema coma.[138] The classic features are hypothermia, delayed DTRs, and an altered sensorium that ranges from stupor to coma. Other predominant features include hypoxia, carbon dioxide retention, severe hypoglycemia, hyponatremia, and paranoid psychosis. Typical physical findings (Table 52-3) include a puffy face and eyelids, a yellowish discoloration of the skin, and loss of the lateral eyebrows. Pleural and pericardial effusions and cardiomegaly may be present. Because myxedema coma frequently occurs in older women, it is often difficult to distinguish the signs and symptoms from dementia or other disease states, as illustrated by R.B. Precipitating factors include cold weather or hypothermia, stress (e.g., surgery, infection, trauma), coexisting disease states such as MI, diabetes, hypoglycemia, or fluid and electrolyte abnormalities (especially hyponatremia), and medications such as sedatives, narcotic analgesics, antidepressants, and other respiratory depressants and diuretics.

Haloperidol and morphine might be responsible for what appears to be impending myxedema coma in R.B. In severely myxedematous patients, respiratory depressants (anesthetics, narcotic analgesics, phenothiazines, sedative-hypnotics) alone or in combination with the hypothermic effects of the phenothiazines can aggravate the preexisting hypothermia and carbon dioxide retention to precipitate myxedema coma.[138,139] Tranquilizers such as haloperidol should not be given; small doses of less depressive sedative-hypnotics such as the benzodiazepines should be used only when necessary. Myxedematous patients are also inherently sensitive to the respiratory depressant effects of narcotic analgesics,

---

especially morphine. A dose as small as 10 mg may induce coma in a hypothyroid patient or cause death in a patient who is already comatose. If morphine is required, the dose should be decreased to one-third to one-half the usual analgesic dose, and the respiratory rate should be monitored closely.

TREATMENT

CASE 52-10, QUESTION 2: What would be a reasonable therapeutic plan for the management of R.B.'s myxedema coma?

Emergency treatment, usually in the intensive care unit, of myxedema coma is directed toward thyroid replacement, maintenance of vital functions, and elimination of precipitating factors. Despite immediate and aggressive therapy with large replacement doses of thyroid, mortality rates of 60% to 70% are common.[138]

Whether T_4 or T_3 is the drug of choice in myxedema coma is controversial because no comparative trials have been conducted. Although T_3 is potentially more cardiotoxic, it has been recommended because its more rapid onset might reverse coma faster, and the peripheral conversion from T_4 to the biologically active T_3 might be inhibited in severe systemic disease.[139–143] T_4 alone, T_3 alone, and a combination of the two have all been used successfully to treat myxedema coma. However, L-thyroxine is generally regarded as the hormone of choice because of greater clinical experience with T_4 than with T_3. Also, mortality has occurred despite the higher T_3 levels achieved after T_3 administration.[143] T_3 might be considered after failure of T_4 or if concomitant systemic illness (e.g., heart failure) is likely to impair conversion of T_4 to T_3. Supraphysiologic elevations in T_3 levels occur only after oral administration but are not seen after IV T_3 infusion. Factors associated with a higher mortality 1 month after therapy include older age, cardiac complications, and T_4 replacement ≥500 mcg/day or T_3 replacement >75 mcg/day.[139,143]

L-Thyroxine 400 to 500 mcg should be given IV initially in patients <55 years of age without cardiac disease to saturate empty TBG sites and raise the serum T_4 level to 6 to 7 mcg/dL.[138,144] This initial dose can be adjusted based on the patient's weight and other restrictive factors (e.g., age, cardiac disease). The initial T_4 dosage for R.B. should be reduced to 300 mcg/day to avoid worsening her angina. If the proper dosage is given, consciousness, restoration of vital signs, and decreased TSH levels should occur within 24 hours. If T_3 is preferred, the usual dose is 10 to 20 mcg IV, followed by 10 mcg every 4 hours for the first 24 hours, and then 10 mcg every 6 hours for a few days until oral therapy can be started.[138]

Maintenance doses should be titrated to the patient's clinical response. Because myxedema can impair oral absorption, the IV route is preferred to ensure adequate drug concentrations. Oral administration is permitted once GI function returns to normal. The smallest dosage (without untoward effects) administered should be 50 to 100 mcg/day of T_4 or 10 to 15 mcg of T_3 every 12 hours.[138,144]

Supportive measures include assisted ventilation, glucose for hypoglycemia, restriction of fluids for hyponatremia, and the use of blood or plasma expanders to prevent circulatory collapse and to maintain blood pressure. The use of blankets to treat R.B.'s hypothermia is not advised because vasodilation will occur and further compromise the cardiovascular components of shock. Although steroids have not been shown to be clearly beneficial in primary myxedema, they may be lifesaving in patients with hypopituitarism masquerading as myxedema coma. Because it is difficult to distinguish between primary and secondary myxedema, hydrocortisone 50 to 100 mg every 6 hours should be given empirically.[138]

Appropriate measures should be taken to relieve R.B.'s chest pain while ruling out the possibility of an MI. The use of a narcotic antagonist such as naloxone may be beneficial in this instance because it can reverse the effects of the morphine. Naloxone can also arouse comatose patients intoxicated with alcohol.

Hypothyroidism with Congestive Heart Failure

CLINICAL PRESENTATION

CASE 52-11

QUESTION 1: E.B., a 45-year-old woman, is admitted with chest pain, SOB, dyspnea on exertion, and orthopnea suggestive of CHF complicated by an MI. Significant past medical history reveals exertional angina and Graves' disease, treated with RAI ablation 10 years ago. Physical examination reveals cardiomegaly, diastolic hypertension, obesity, facial edema and puffiness, delayed DTRs, and non-pitting pretibial edema. Pertinent laboratory findings include the following results:

FT_4, 0.2 ng/dL (normal, 0.8–1.4)
TSH, 100 microunits/mL (normal, 0.45–4.1)
Creatinine phosphokinase, 300 units/L with negative MB bands
Aspartate aminotransferase (AST), 80 units/L
Lactate dehydrogenase (LDH), 250 units/L
Brain natriuretic peptide, 550 pg/mL
Troponin, 0.3 ng/mL (normal, 0.3–1.5)

A chest radiograph reveals cardiomegaly and pericardial effusions, and an electrocardiogram (ECG) shows bradycardia and flattened T waves with ST depression. Furosemide, nitrates, metropolol, and Lisinopril are started. E.B.'s symptoms improve, but her cardiac abnormalities are not reversed.

Why do these clinical findings suggest hypothyroidism?

E.B.'s abnormal thyroid function tests, symptoms, physical findings, and history of RAI therapy are consistent with severe hypothyroidism. "Myxedema heart" can be confused with low-output CHF because the symptoms are similar: cardiomegaly, dyspnea, edema, pericardial effusions, and abnormal ECG.[85,138] Therefore, hypothyroidism should be ruled out in all patients with new or worsening symptoms of cardiovascular disease (e.g., angina, arrhythmia). Although hypothyroidism alone rarely causes CHF, it can worsen an underlying cardiac condition. Rarely, ventricular arrhythmia, including torsades de pointes, can occur from a prolonged QT interval.

Although E.B.'s enzyme elevations (i.e., AST, CK, LDH, CPK) are suggestive of an MI, they all may be moderately or significantly increased from chronic skeletal or cardiac muscle damage or from decreased enzyme clearance secondary to hypothyroidism. The normal troponin level and negative CPK-MB bands eliminate the likelihood of an MI.

TREATMENT

CASE 52-11, QUESTION 2: What might be the effect of hypothyroidism on the cardiac treatment and status of E.B.?

If E.B.'s cardiac abnormalities are caused by hypothyroidism, adequate doses of T_4 will restore the heart size, normalize the diastolic blood pressure, reverse the ECG findings, and normalize the serum enzyme elevations within 2 to 4 weeks.

However, improvement in myocardial function begins only at dosages of 50 to 75 mcg/day of T_4, which may be tolerated poorly by cardiac patients.

The relationship between the altered lipid metabolism of hypothyroidism and increased risk of atherosclerosis is controversial and poorly documented.[137] Angina pectoris and MI are

---

rather uncommon among hypothyroid patients. Theoretically, the hypometabolic state occurring in hypothyroidism may protect the ischemic myocardium by reducing metabolic demands. However, hypothyroidism actually aggravates sub-endocardial ischemia during an acute MI by decreasing erythrocyte production of 2,3-diphosphoglycerate, which shifts the oxyhemoglobin dissociation curve to the left. This effect further diminishes oxygen delivery to already ischemic tissues. Angina or premature beats can develop or worsen with the institution of T_4 therapy,[145–147]so doses should be titrated carefully (see Case 52-11, Question 3). Without organic disease, digitalis is ineffective and may even be harmful. Hypothyroid patients show an increased sensitivity to digitalis, and digitalis toxicity is possible unless the maintenance dose is decreased (see Case 52-14, Question 3).[148,149] Nitrates may precipitate hypotension and/or syncope in hypothyroid patients because these patients have a low circulating blood volume and their response to vasodilation can be exaggerated. Furthermore, if β-blockers are required, the cardioselective β-blockers are preferred. The non-cardioselective β-blockers have produced coronary spasm by exacerbating the compensatory increase in norepinephrine levels and α-adrenergic tone found in hypothyroidism.

CASE 52-11, QUESTION 3: How aggressively should thyroid hormone therapy be initiated in a patient like E.B. who has angina? What is the hormone replacement of choice in patients with cardiac disease?

Patients with long-standing hypothyroidism, arteriosclerotic cardiac disease, or advanced age tend to be extremely sensitive to the cardiac effects of thyroid hormone. Initiation of normal or even subtherapeutic doses might produce severe angina, MI, supra- and ventricular premature beats, cardiac failure, or sudden death and underscore the need to replace thyroid cautiously, and sometimes suboptimally, to avoid cardiac toxicity.[145–147],[150]

The angina and cardiac status should be controlled before initiating T_4 therapy. In the patient with poorly controlled angina, cardiac catheterization is warranted to assess the coronary artery status before starting hormone therapy. Coronary bypass has been performed safely with minimal complications in the hypothyroid patient to control the angina and may allow institution of full replacement doses without cardiotoxicity.[151]

For E.B., 12.5 to 25 mcg daily of T_4 should be initiated cautiously and increased as tolerated by similar increments of T_4 every 4 to 6 weeks until a therapeutic dosage is reached. The rapidity with which the increments can proceed is determined by how well each increased dose is tolerated. If cardiac toxicity occurs, therapy should be stopped immediately. Once symptoms resolve, therapy can be restarted using smaller dosage increments and longer intervals between dosage adjustments. If cardiac symptoms recur, further T_4 therapy should be stopped pending cardiac evaluation. In patients with severe cardiac sensitivity, complete euthyroidism might never be achieved, and the correct replacement dosage is a compromise between prevention of myxedema and avoidance of cardiac toxicity.[147] E.B.'s clinical status and ECG should be monitored closely during the titration period. T_4 should be discontinued or decreased at the first sign of cardiac deterioration. It is not necessary to monitor thyroid function tests (e.g., TSH or FT_4) during the titration period because the results will remain low until adequate replacement is achieved. Thyroid function tests should be obtained once maximally tolerated or estimated euthyroid dosages are achieved.

Some suggest that T_3 is the agent of choice in patients with cardiac abnormalities because of its shorter duration of action. After therapy is withdrawn, the effects of T_3 dissipate in 3 to 5 days, compared to 7 to 10 for T_4. Thus, if toxicity occurs, the effects of T_3 will disappear rapidly on cessation of therapy, a theoretical advantage in the cardiac patient. Nevertheless, T_3 is not recommended because its greater potency requires finer and more difficult dosage titration to ensure smooth and uniform blood levels. Furthermore, the high serum T_3 levels that occur after oral administration might cause more cardiac toxicity, especially angina.

Subclinical Hypothyroidism

CASE 52-12

QUESTION 1: M.P., a healthy 53-year-old woman, comes in for her regular checkup. She denies any symptoms of hypothyroidism and feels well. She has no other medical problems, takes no medications, and has no known allergies. Her physical examination is within normal limits. Routine screening laboratory tests are normal except for an FT_4 of 1.2 ng/dL (normal, 0.8–1.4) and a TSH of 8 microunits/mL (normal, 0.45–4.1). Does M.P. require thyroid treatment, based on her clinical presentation and laboratory findings?

M.P.'s free thyroid levels are normal, but her TSH level is elevated, indicating subclinical hypothyroidism (SH). The prevalence of SH ranges from 4% to 10% and increases to 26% in the elderly population, particularly women.[87,88] It is unclear whether SH represents the early stages of thyroid failure. The estimated risk of developing overt hypothyroidism after 10 years in untreated patients by Kaplan–Meier curves was 0% for a TSH level of 4 to 6 microunits/mL, 42.8% for a TSH level of 6 to 12 microunits/mL, and 76.9% for a TSH level >12 microunits/mL. This risk increased in patients with positive thyroid antibodies.[152] Because the most common clinical scenarios involve asymptomatic patients with TSH levels <10 microunits/mL, negative thyroid antibodies, and no history of prior thyroid disease, routine thyroid screening has been recommended, particularly in elderly women.[88]

Mild symptoms of hypothyroidism, including psychiatric and cognitive abnormalities, are found in approximately 30% of patients with SH, but the average TSH level usually exceeds 11 microunits/mL. Cardiac dysfunction, including impaired left ventricular diastolic function at rest, systolic dysfunction with exercise, atherosclerosis, CHF, and MI has been reported.[85,88,153–155] Data showing an increased risk of coronary heart disease (CHD) are conflicting and influenced by the severity of SH, study design, and length of follow-up. A meta-analysis noted a 1.6 times increased risk of CHD,[156] a cross-sectional analysis noted an odds ratio of 2.2 only in those with TSH levels of ≥10 microunits/mL, whereas a 20-year longitudinal analysis found a significant risk (hazard ratio (HR) of 1.7) regardless of the degree of TSH elevation.[157] However, a large prospective cohort study found no significant association with atherosclerotic disease or cardiac mortality but observed an increase in all-cause mortality at 10 years of follow-up.[158] Compelling data reported from 11 large prospective cohorts with a median follow-up of 2.5 to 20 years involving 3,450 subjects with subclinical hypothyroidism found an increased risk of CHD (HR 1.89) and mortality (HR 1.5) but not total mortality only in those with TSH level >10 microunits/mL after adjustment for traditional cardiovascular factors. No increased CHD or CHD mortality was noted with more minimal TSH elevations.[159]

Other atypical and nonspecific signs and symptoms reflecting dysfunction of any part of the body may occur, primarily in the elderly. Failure to thrive, mental confusion, weight loss with poor appetite, incontinence, depression, inability to walk, carpal tunnel syndrome, deafness, ileus, anemia, hypercholesterolemia, and hyponatremia have been reported.[87,88,153–155]

Treatment of subclinical hypothyroidism with T_4 is controversial because study results are conflicting. Potential benefits of

---

treatment include (a) preventing progression to hypothyroidism, (b) improving the lipid profile and reducing cardiac risks, and (c) reversing symptoms of hypothyroidism. Patients with higher TSH levels (e.g., >10 microunits/mL), a history of previously diagnosed thyroid disease, elevated lipid levels, or evidence of positive thyroid antibodies gained the most benefit from L-thyroxine therapy.[85,88,152,155,160] L-Thyroxine significantly reduced total cholesterol by 7.9–15.8 mg/dL and low-density cholesterol concentrations by 10 mg/dL; serum HDL cholesterol and triglyceride concentrations remain unchanged.[88,154,155,160] Improvement of elevated intraocular pressures, memory, mood, somatic complaints, and diastolic dysfunction has also been reported after T_4 replacement.[152,154,155,160]

Treatment of older patients requires an assessment of the risks versus benefits of therapy. Thyroid therapy carries the risk of unmasking underlying cardiac disease in older patients. Nevertheless, thyroid replacement appears reasonable in asymptomatic patients with TSH levels >10 microunits/mL and especially those with symptoms of mild hypothyroidism, dyslipidemia, laboratory abnormalities, or end-organ alterations.[87,88,152,154,160] Patients with mild subclinical hypothyroidism (TSH 6–10 microunits/mL) may benefit from therapy with L-thyroxine 25 to 75 mcg/day when there is evidence of cardiovascular risk (e.g., diastolic dysfunction, risk of atherosclerotic disease, diabetes) or clinical indicators suggestive of hypothyroidism (e.g., goiter, antibodies).[88] There is no evidence supporting the treatment of mild subclinical disease in patients over 80 years of age.[88] Conversely, patients with asymptomatic subclinical hypothyroidism and a TSH level <10 microunits/mL do not warrant immediate therapy, but close follow-up is recommended.

Because M.P. is asymptomatic and has a TSH level <10 microunits/mL, it is reasonable to delay therapy and recheck the TSH in a few months.

Hypopituitarism and Thyroxine Replacement with a Normal Thyroid-Stimulating Hormone Level

CASE 52-13

QUESTION 1: J.P. is a 65-year-old woman who complains of fatigue, cold intolerance, dry skin, and weight gain for the past several months. Her thyroid examination and DTRs are within normal limits. A TSH level was 2.5 microunits/mL (normal, 0.45–4.1). She denies taking any other medications. J.P. is started empirically on a 3-month trial of L-thyroxine. How should the TSH level be interpreted? Is T_4 therapy indicated based on her presenting findings?

Despite complaints that could be consistent with hypothyroidism (e.g., fatigue, cold intolerance, dry skin, weight gain), the normal TSH level indicates that J.P. is euthyroid. However, because a diagnosis of hypopituitarism (i.e., TSH level could be normal or low) cannot be ruled out, an FT_4 level should be obtained; a low level would increase the likelihood of hypopituitarism. Some argue that hypopituitarism is underdiagnosed and would advocate adding FT_4 to the primary screening tests.[161]

If the FT_4 level is normal, indicating euthyroidism, then hypopituitarism is unlikely and L-thyroxine therapy is not indicated. A randomized, double-blind, placebo-controlled crossover trial found that T_4 supplementation in patients with hypothyroid symptoms and normal thyroid function tests was not more effective than placebo in improving cognitive function or psychologic well-being despite changes in the TSH and FT_4 levels.[162,163]

In J.P., the T_4 should be discontinued because there is no evidence of its efficacy in euthyroid individuals.

HYPERTHYROIDISM

Clinical Presentation

CASE 52-14

QUESTION 1: S.K., a 48-year-old woman, is admitted to the hospital for a possible MI. Her complaints include chest pain that is unrelieved by NTG, increasing SOB with exercise, nervousness, palpitations, muscle weakness, weight loss despite an increased appetite, and epistaxis; she also bruises easily. She has a history of deep venous thrombosis treated with warfarin 5 mg/day; her last international normalized ratio (INR) was 1.8 (normal, 1; therapeutic, 2–3). She has angina, treated with NTG 0.4 mg, and CHF, treated with digoxin 0.25 mg/day.

Physical examination reveals a thin, flushed, hyperkinetic, nervous woman. Blood pressure (BP) is 180/90 mmHg; pulse is 130 beats/minute, irregularly irregular; respiratory rate is 30 breaths/minute; and temperature is 37.5°C. Other pertinent findings include a lid lag with stare, proptosis with tearing, decreased visual acuity, a diffusely enlarged thyroid gland without nodules, a bruit in the left lobe of the thyroid, positive jugular venous distention (JVD), bibasilar rales, warm moist skin with multiple bruises, new-onset atrial fibrillation (AF), slight diarrhea, hepatomegaly, acropachy, 2+ pitting edema, a fine tremor, proximal muscle weakness, and irregular scant menses.

Laboratory data include the following results:

FT_4, 2.9 ng/dL (normal, 0.8–1.4)
TSH, <0.5 microunits/mL (normal, 0.45–4.1)
RAIU at 24 hours, 80% (normal, 5%–35%)
INR, 4.8 (normal, 1; therapeutic, 2–3)
TPOAb, 200 IU/mL (normal, <0.8)
Alkaline phosphatase, 200 units/L
Total bilirubin, 1.1 mg/dL
AST, 60 units/L
Alanine aminotransferase, 55 units/L

A RAI scan shows a diffusely enlarged gland, 3 to 4 times the normal size. What subjective and objective data are suggestive of hyperthyroidism in S.K.?

S.K. presents with many of the clinical and laboratory features[164] associated with an increased metabolic state resulting from excessive T_4 (Table 52-5). Her ocular symptoms are consistent with Graves' disease and include lid lag (lid falls behind the movement of the eye and a narrow white rim of sclera becomes visible between the upper lid and cornea, producing a "staring" appearance), ophthalmopathy (protrusion of the eyeball), and decreased visual acuity. The thyroid bruit, palpitations, exertional dyspnea, worsening CHF (JVD, bibasilar rales, edema, hepatomegaly), diarrhea, irregular scant menses, nervousness, tremor, muscle weakness, weight loss despite increased appetite, increased perspiration, and flushing of the skin are consistent with a hypermetabolic state. Although sinus tachycardia is the most common arrhythmia in hyperthyroidism, new-onset AF is the presenting symptom in 5% to 20% of patients with hyperthyroidism, particularly in those older than 70 years.[165] Together with S.K.'s symptoms, a diagnosis of Graves' disease is confirmed by an elevated FT_4 level, an undetectable TSH level, an increased RAIU, positive TPOAb, and a diffusely enlarged goiter. Her cardiac status and other medical problems are aggravated by the hyperthyroidism. (Table 52-6 lists the causes of hyperthyroidism.)

Hypoprothrombinemia

CASE 52-14, QUESTION 2: What factors contribute to S.K.'s hypoprothrombinemia? What effect could this have on her subsequent drug treatment?

The hypoprothrombinemia and bleeding observed in S.K. are most likely related to an exaggerated response to warfarin. This may be related to a decrease in the hepatic metabolism of warfarin (secondary to hepatic congestion), but it is more likely that S.K.'s findings are because of the combined effects of hyperthyroidism and warfarin on vitamin K–dependent clotting factors.

WARFARIN METABOLISM

Warfarin metabolism and the metabolism of vitamin K–dependent clotting factors can be altered by thyroid status. Net circulating levels of vitamin K–dependent clotting factors are generally not altered in hyperthyroid patients because both the synthesis and catabolism of these clotting factors are increased. However, an enhanced anticoagulant response occurs when the warfarin-induced decrease in clotting factor synthesis is combined with the hyperthyroidism-induced increase in clotting factor catabolism.[12,166] This may explain S.K.'s elevated INR, bruising, and history of epistaxis.

The opposite occurs in hypothyroidism, in which a decrease in both the metabolism and synthesis of clotting factors occurs. In hypothyroid patients, the response to oral anticoagulants is delayed because the clotting factors are eliminated more slowly.[12,166] Therefore, hyperthyroid patients need less warfarin, whereas hypothyroid patients require more warfarin to achieve the same hypoprothrombinemic response. The anticoagulant response to warfarin should be monitored carefully in patients with thyroid abnormalities, and the dosage adjusted as the thyroid status changes.

THIOAMIDE EFFECTS

Because S.K.'s hyperthyroidism will most likely be treated with a thioamide, caution must be exercised. Treatment of hyperthyroid patients with thioamides, especially PTU, has been associated with hypoprothrombinemia, thrombocytopenia, and bleeding, albeit rarely.[167] These drugs can depress the bone marrow and the synthesis of clotting factors II, III, VII, IX, X, and XIII; vitamin K and prothrombin times may remain depressed for up to 2 months after discontinuation of therapy. These effects may be caused by a subclinical hepatic alteration in synthesis or hepatotoxicity (see Case 52-15, Question 10).[30,168–171] Symptoms occur 2 weeks to 18 months after starting therapy. The bleeding is responsive to vitamin K or blood transfusions. (Also see Case 52-15, Questions 3 and 4 for further discussion of treatment with thioamides.)

Response to Digoxin

CASE 52-14, QUESTION 3: S.K.'s dose of digoxin was increased to 0.5 mg daily because of persistent AF with a rapid ventricular response. Why was such a large dose of digoxin required? What other options can be used to control her ventricular rate?

The AF of hyperthyroidism is often resistant to digitalis. When euthyroid patients with AF were given digitalis before and after exogenous T_3 administration, the daily dose of digoxin required to maintain a ventricular rate of 70 was increased from 0.2 to 0.8 mg after T_3 administration.[172] Higher dosages of digoxin without side effects might be tolerated better by the hyperthyroid patient.[148,149,172] Nevertheless, the goal of digoxin therapy should be a higher target heart rate (i.e., 100 beats/minute) than that achieved with digoxin in the euthyroid patient with AF to minimize cardiac toxicity. If additional rate control is required, β-blockers or calcium channel blockers (e.g., diltiazem or verapamil) can be added. Unless contraindicated by severe bronchospasm, β-blockers rather than calcium channel blockers are preferred because they are more effective in controlling the ventricular rate and are less likely to cause hypotension.

This apparent resistance to digitalis is attributed to intrinsic changes in myocardial function, to an increased volume of distribution for digoxin, and to an increased glomerular filtration of the glycoside.[148,149,172] Conversely, hypothyroid patients are inordinately sensitive to the effects of digitalis and require smaller doses to achieve a therapeutic response. Regardless of the mechanism, one should be aware that higher-than-normal doses might be required in patients with thyrotoxicosis and that the initial dosage should be reduced as the hyperthyroid state resolves.

S.K. should be maintained on warfarin because of a high prevalence of systemic embolization in thyrotoxic patients with AF. Anticoagulation should be started when the AF is first diagnosed and continued until S.K. is euthyroid and in NSR. This is especially true for younger patients at low risk of bleeding with warfarin. The risks versus benefits of anticoagulation should be weighed before therapy (see Chapter

16). Because an increased sensitivity to warfarin is observed, close monitoring is warranted (see Case 52-14, Question 2). Cardioversion, either medical or electrical, should not be attempted if she is still toxic because the success rate is low. If cardioversion is to be used, it should not be attempted until the third or fourth month after achieving euthyroidism.[165]

T_3 Thyrotoxicosis: Clinical Presentation

CASE 52-15

QUESTION 1: C.R., a 27-year-old woman, has a 3-month history of intermittent heat intolerance, sweats, tremor, and severe muscle weakness, which has limited her ability to climb stairs. Her weight has increased because of increased appetite. She is also bothered by the pounding of her heart and some minor difficulty in swallowing. There is a family history of thyroid disease, but she denies taking any thyroid medications or any history of radiation to her neck. C.R. previously received iodide drops with symptomatic improvement, but her disease recurred despite its continued administration. Her other medical problems include type 2 diabetes controlled by diet, and osteoarthritis treated with aspirin 650 mg PO q4h. She has a history of noncompliance with her clinic visits.

Pertinent physical findings include a BP of 180/90 mmHg, a pulse of 110 beats/minute, hyperreflexia, lid lag, and a diffusely enlarged thyroid gland that is about 4 times normal (about 100 g). Laboratory data include the following:

TT_4, 6 mcg/dL (normal, 4.8–10.4)
FT_4, 2 ng/dL (normal, 0.8–1.4)
TSH, <0.01 microunits/mL (normal, 0.45–4.1)
TPOAb, 350 IU/mL (normal, <0.8)
Fasting blood glucose, 350 mg/dL
Assess these subjective and objective data.

C.R.'s laboratory findings of a positive TPOAb and elevated thyroid hormone levels verify an autoimmune hyperthyroid state. However, the serum FT_4 is elevated only slightly and is disproportionately low relative to the severity of her symptoms, the undetectable TSH level, and her other laboratory findings. The low normal TT_4 could be explained by displacement of T_4 from TBG by aspirin (see Case 52-2). The possibility of a variant type of hyperthyroidism known as T_3 toxicosis should be considered. The clinical features include signs and symptoms of thyrotoxicosis, normal or borderline high FT_4, an undetectable TSH level, and elevated T_3 levels. The latter occurs through preferential secretion and peripheral conversion of T_4 to T_3. A T_3 level should be obtained to establish the diagnosis.

Asymptomatic elevations of T_3 levels often precede elevation of T_4 levels and the development of overt hyperthyroidism. T_3 toxicosis probably represents an early stage of classic T_4 toxicosis and is useful for early diagnosis or as an early indicator of relapse after discontinuation of thioamide therapy.

Iodides

CASE 52-15, QUESTION 2: Why were the iodide drops initially effective in improving C.R.'s symptoms and later ineffective? When are iodides indicated? What is their mechanism of action?

Iodides have several effects: They inhibit thyroid hormone release, they block iodotyrosine and iodothyronine synthesis by blocking organification, and they decrease the vascularity of the thyroid gland.[173] However, large doses may accentuate hyperthyroidism because they provide a significant increase in available substrate for hormone synthesis (see Case 52-24).[28,173]

The inhibitory effect of exogenous iodides on the intrathyroidal organification of iodides is known as the Wolff–Chaikoff effect. This is an inherent autoregulatory function of the normal gland to prevent excessive hormone synthesis in the event of a large iodide load. The Wolff–Chaikoff effect occurs when intrathyroidal concentrations of iodides reach a critical level, and this is not overcome by TSH stimulation. However, as illustrated by C.R., the gland can "escape" from this block even with continued iodide use. The gland escapes by decreasing iodide transport or by leaking iodide. Both mechanisms decrease the critical intrathyroidal iodide level, thereby decreasing the block to organification. This effect is illustrated in C.R. Therefore, iodides should not be used as primary therapy for Graves' disease.

Conversely, some patients are responsive to iodide therapy, including (a) patients who already have high intrathyroidal iodine stores (i.e., "hot" nodules, Graves' disease); (b) patients with underlying defects in organic binding mechanisms (i.e., Hashimoto's); (c) patients who develop drug-induced thyroid disorders (see Cases 52-23 and 52-24); and (d) patients with Graves' disease made euthyroid with RAI or surgery and who are receiving no thyroid replacement.

These patients are so sensitive that small doses of iodide can elicit the Wolff–Chaikoff effect, resulting in either amelioration of hyperthyroid symptoms or precipitation of hypothyroidism.[16,28,173] For this reason, patients with recurrent hyperthyroidism after surgery or RAI can often be managed with iodides alone.

The most important pharmacologic effect of iodides is their ability to promptly inhibit thyroid hormone release when dosages of 6 mg/day are given.[16,173] The mechanism is unknown, but it is not related to the Wolff–Chaikoff effect, which may take several weeks to manifest. Unlike the Wolff–Chaikoff effect, this effect can be overcome partially by an increase in TSH secretion. Thus, the normal gland can escape in 7 to 14 days because inhibition of thyroid hormone release stimulates a reflex increase in TSH secretion. Because patients with hyperthyroidism experience an improvement in symptoms within 2 to 7 days of initiation of therapy, inhibition of hormone release must be the predominant mechanism of action for the iodides. This rapid onset is the reason iodides are used in the treatment of thyroid storm and as an ameliorative measure while awaiting the onset of the therapeutic effects of thioamides or RAI.

Large doses of iodides are also used 2 weeks before thyroid surgery to increase the firmness of the thyroid gland by decreasing its size, vascularity, and friability. Iodides facilitate a smoother, less complicated surgery and reduce the risk of postoperative complications by inducing a euthyroid state.[173]

Stable iodine can be administered orally either as an unpleasant-tasting Lugol's solution (5% iodine and 10% potassium iodide), containing 8 mg/drop of iodide, or as the more palatable saturated solution of potassium iodide (SSKI), containing 50 mg/drop of iodide. The minimum effective daily dose is 6 mg,[173] although larger doses (e.g., 5–10 drops QID of SSKI) are often administered.

The advantages of iodide therapy are that it is simple, inexpensive, and relatively nontoxic and involves no glandular destruction. Disadvantages include "escape," accentuation of thyrotoxicosis, allergic reactions, relapse after discontinuation of treatment, and subsequent interference with RAI if used before therapy.

Treatment Modalities

CASE 52-15, QUESTION 3: What are the advantages and disadvantages of the different treatment modalities available for C.R.?

The three major treatment modalities for Graves'-related hyperthyroidism are the thioamides, RAI, and surgery (Table 52-10).[164] In most cases, any of these three modalities can be used, and there is controversy as to which is the most effective therapy. Often the final decision is empiric, depending on the clinician's available resources and the patient's desires. A review of treatment guidelines published by the major endocrine organizations found that RAI is the most common treatment, while surgery is the least common.[174] Patients who are older and those with cardiac disease, concomitant ophthalmopathy, and hyperthyroidism caused by a toxic multinodular goiter are treated best with RAI. Surgery is the preferred therapy for pregnant women who are drug intolerant, when obstructive symptoms are present, or if malignancy is suspected.

THIOAMIDES

The thioamides are the preferred treatment for children, pregnant women, and young adults with uncomplicated Graves' disease.[164,175,176] This is the only treatment that leaves the thyroid gland intact and does not carry the added risk of permanent hypothyroidism often associated with RAI or surgery.

Because the thyrotoxicosis of Graves' disease might be self-limiting, thioamides are used to control the symptoms until spontaneous remission occurs. Thioamides should also be given before treatment with RAI or surgery to deplete the gland of stored thyroid hormone, which prevents subsequent thyroid storm. Although hyperthyroidism from toxic nodules will also respond to thioamides, more definitive therapy (surgery or RAI) is needed because these conditions do not undergo spontaneous remission.

Disadvantages of thioamide therapy include the numerous tablets required, patient adherence, possible drug toxicity, the long duration of treatment, and the low remission rates after discontinuation of therapy (see Case 52-16).

The use of thioamides in C.R. has several potential drawbacks. Her relatively large gland and severe disease make the prognosis for spontaneous remission somewhat less favorable. A delay in the onset of thioamide's effect may be expected if intraglandular stores of thyroid have been increased by her prior iodide therapy. Furthermore, her non-adherence and difficulty swallowing may necessitate another means of treatment. Thioamides may also be prepared for administration by the rectal routes.[177–179]

SURGERY

Surgery is considered the treatment of choice[164,180–182] when (a) malignancy is suspected; (b) esophageal obstruction, evidenced by difficulty swallowing, is present; (c) respiratory difficulties are present; (d) contraindications to the use of thioamides (e.g., allergy) or RAI (e.g., pregnancy) exist; (e) a large goiter that regresses poorly on RAI or thioamide therapy is present; or (f) it is the patient's preference. Some argue that surgery is underused in the treatment of Graves' disease.[180] In a prospective, randomized trial comparing the three treatment modalities, surgery produced euthyroidism more quickly and was associated with a lower relapse rate than either RAI or thioamides.[181] A meta-analysis of 35 studies encompassing 7,241 patients with Graves' disease found that thyroidectomy was successful in 92% of patients with a low recurrence (7.2%) of hyperthyroidism.[183] If C.R.'s minor difficulty in swallowing persists because of poor regression of goiter size with drug therapy, then surgery is a reasonable alternative. If surgery is contemplated, C.R. must be brought to surgery in a euthyroid state to prevent rapid postoperative rises in T_4 levels and subsequent thyroid storm (see Case 52-22, Question 1). A total or near-total rather than a subtotal thyroidectomy is the procedure of choice when performed by an experienced surgeon.[180,182,183] Although subtotal thyroidectomy theoretically avoids the predictable risk of hypothyroidism from total thyroidectomy, the likelihood of recurrent hyperthyroidism increases in proportion to the amount of residual thyroid tissue remaining.[180,181] Recurrent thyrotoxicosis following a subtotal thyroidectomy should be treated with RAI because the incidence of surgical complications increases with a second surgery.

Table 52-10

Treatment for Hyperthyroidism

Modality	Drug/Dosage	Mechanism of Action	Toxicity	Indication
Primary Treatment				
Thioamides				
Methimazole (Tapazole) 5-, 10-mg tablet; rectal suppositories can be made[179]	Methimazole 30–40 mg PO daily or in 2 divided doses (max: 60 mg/day) for 6–8 weeks or until euthyroid, then maintenance of 5–10 mg/d PO × 12–18 months	Blocks organification of hormone synthesis, does not block conversion of T_4 to T_3	Skin rashes, GI symptoms, arthralgias, cholestatic jaundice, agranulocytosis, aplasia cutis, and embryopathy syndrome in pregnancy (methimazole only)	DOC in adults/children except in thyroid storm and first trimester of pregnancy (see PTU). Once daily dosing can improve adherence
PTU 50 mg tablet; rectal formulation can be made[177,178]	100–200 mg PO q6–8h (max: 1,200 mg/day) for 6–8 weeks or until euthyroid; then maintenance of 50–150 mg daily PO × 12–18 months	Similar to methimazole, and blocks peripheral conversion of T_4 to T_3 (PTU only)	Hepatitis, some fatal. Similar to methimazole	DOC in thyroid storm, first trimester of pregnancy
Surgery				
	Preoperative preparation with iodides, thioamides, or β-blockers before surgery; see specific operative agent	Near total thyroidectomy	Hypothyroidism, cosmetic scarring, hypoparathyroidism, risks of surgery, and anesthesia, vocal cord damage	Obstruction, choking, malignancy, pregnancy in second trimester, contraindication to RAI or thioamides
RAI				
	^{131}I radioactive isotope; 80–100 µCi/g thyroid tissue. Average dose, ≈10 mCi; pretreatment with corticosteroids indicated in patients with ophthalmopathy	Destruction of the gland	Hypothyroidism; worsening of ophthalmopathy; fear of radiation-induced leukemia; genetic damage; malignancy; rarely, radiation sickness	Adults, older patients who are poor surgical risks or have cardiac disease; patients with a history of prior thyroid surgery; contraindications to thioamide usage; increasingly used in kids
Adjuncts to Primary Usage				
Iodides				
Lugol's solution 8 mg/drop (5% iodine, 10% potassium iodide;	5–10 drops TID PO for 10–14 days before surgery; minimum effective dose 6 mg/day	↓ vascularity of gland and ↑ firmness; blocks release of thyroid hormone	Hypersensitivity reactions, skin rashes, mucous membrane ulcers, anaphylaxis, metallic taste, rhinorrhea,	Preoperative preparation before surgery; thyroid storm, provides symptomatic relief of symptoms. Do not use before RAI or chronically

saturated [SSKI] 50 mg/drop)			parotid and submaxillary swelling; fetal goiters and death	during pregnancy
β-Blockers				
Propranolol or equivalent β-blocker. Avoid those with ISA	Propranolol 10–40 mg PO q6h or PRN to control HR <100 beats/minute; IV 0.5–1 mg slowly	Blocks effects of thyroid hormone peripherally, no effect on underlying disease; blocks T_4 to T_3 conversion	Related to β-blockade; bradycardia, CHF, blocks hyperglycemic response to hypoglycemia, bronchospasm, CNS symptoms at high doses; fetal bradycardia	Symptomatic relief while awaiting onset of thioamides, RAI; preoperative preparation for surgery; thyroid storm
Calcium Channel Blockers				
	Diltiazem 120 mg PO TID–QID or verapamil 80–120 mg PO TID–QID PRN to control HR <100 beats/min	Blocks effects of thyroid hormone peripherally, no effect on underlying disease	Bradycardia, peripheral edema, CHF, headache, flushing, hypotension, dizziness	Alternative for symptomatic relief of hyperthyroid symptoms in patients who cannot tolerate β-blockers
Corticosteroids				
	Prednisone or equivalent corticosteroids 50–140 mg PO daily in divided doses; IV hydrocortisone 50–100 mg q6h or equivalent for thyroid storm	↓ TSI, suppression of inflammatory process; blocks T_4 to T_3 conversion	Complications of steroid therapy	Ophthalmopathy, thyroid storm (use IV steroid), pretibial myxedema, pretreatment before RAI therapy in patients with ophthalmopathy

p. 1060

Surgical complication rates are low when the procedure is performed by a competent surgeon and when the patient is adequately prepared for surgery. The disadvantages of surgery are expense, hospitalization, hypothyroidism, the small risk of postoperative complications, and the patient's fear of surgery (see Case 52-15, Question 12).[180,181,183]

RADIOACTIVE IODINE

RAI, the most common treatment modality in the United States, is the preferred treatment for (a) debilitated, cardiac, or older patients who are poor surgical candidates; (b) patients who fail to respond to drug therapy or who experience adverse drug reactions; and (c) patients who develop recurrent hyperthyroidism after surgery.[164,174,181,184]

Pregnancy is an absolute contraindication to RAI therapy. Previously, the use of RAI was restricted to adults older than an arbitrary age of 20 to 35 years because it was feared that RAI could result in genetic damage or neoplasia. However, its use in adolescents is increasing after more than 50 years of clinical experience with RAI showing that it is safe and effective.[184–187] There is no reported evidence of genetic damage after ^{131}I ingestion, and the dose of radiation to the gonads is <3 rads, which is comparable to other radiographic diagnostic tests (e.g., barium enemas).[188] The incidence of leukemia or malignancy is no higher in recipients of ^{131}I than in thyrotoxic patients treated with drugs or surgery.[185,189] In a retrospective review of 98 adolescents followed for 36 years after receiving ^{131}I, no cancers of the thyroid or leukemia were reported.[187] One interesting finding is that patients receiving RAI should be warned that they can set off radiation detectors at airport screening terminals for up to 12 weeks after RAI and that they should carry documentation of their treatment.[190,191]

RAI is painless, effective, economical, and quick, but unsubstantiated fears about radiation and malignancy, as well as the high incidence of hypothyroidism, may deter its use. RAI could be used safely in this nonpregnant young patient. However, C.R.'s prior use of iodides will dilute the ^{131}I pool. Thus, it will be impossible to achieve therapeutic thyroid concentrations of RAI for as long as 3 to 6 months.

Treatment with Thioamides

PROPYLTHIOURACIL VERSUS METHIMAZOLE

CASE 52-15, QUESTION 4: C.R. is started on PTU 200 mg q8h after baseline FT_4 and TSH levels have been obtained. Three weeks later, she angrily complains that her symptoms are worse and that the medication is not working; however, she reluctantly admits to missing doses because of difficulty swallowing, nausea, vomiting, diarrhea, fatigue, a cough, and a sore throat. What are the advantages of using either PTU or methimazole in the treatment of hyperthyroidism?

Both thioamides are effective in treating hyperthyroidism. The antithyroid effectiveness of the thioamides primarily depends on their ability to block the organification of iodines, thereby inhibiting thyroid hormone synthesis.[175,176] Thyroid autoantibody synthesis may also be suppressed. In most hyperthyroid adults and children, methimazole should be considered the thioamide of choice because of increasing reports of hepatitis, some fatal, from PTU. PTU should be reserved for use in thyroid storm, during the first trimester of pregnancy because of rare teratogenicity from methimazole, and in those allergic to methimazole (except agranulocytosis and hepatitis) who are not candidates for RAI or surgery.[30,169]

Dosing and Administration

Methimazole is effective when administered initially as a single dose compared with the multiple-dose regimen required with PTU to achieve a euthyroid state.[175,176] Although a single-dose regimen of PTU has been tried acutely, it is most effective when given in divided doses. Compared to PTU, methimazole is also less hepatototoxic, less expensive, requires daily ingestion of fewer numbers of tablets, and is not associated with a bitter tablet taste. However, PTU is preferred in thyroid storm because, unlike methimazole, it also blocks the peripheral conversion of T_4 to T_3.[192] Within 24 to 48 hours after PTU administration, a 25% to 40% reduction in peripheral T_3 production is seen, which contributes to PTU's rapid onset. A significantly greater fall in T_3 concentration and the T_3:T_4 ratio can be demonstrated in hyperthyroid patients treated acutely with PTU and iodine than with methimazole and iodides. Lastly, PTU is preferred over methimazole during the first trimester of pregnancy (see Case 52-18).

CASE 52-15, QUESTION 5: Why was the thioamide therapy ineffective in C.R.? Was the dose of PTU appropriate?

The inadequate response in C.R. suggests poor adherence to the thioamide dosing regimen or a delayed response caused by prior iodide loading of the gland.

The onset of action of the thioamides is slow because they block the synthesis rather than the release of thyroid hormone. Therefore, hormone secretion will continue until the glandular stores of hormone are depleted. If adequate doses were given, some improvement of clinical symptoms should be noted after 2 or 3 weeks.[176]

The dosage of PTU is appropriate. Thioamide dosing consists of two phases: initial therapy to achieve euthyroidism and maintenance therapy to achieve remission. Initially, high blocking dosages of PTU (400–800 mg/day, depending on the severity of the toxicosis) should be given in three or four divided doses, as in C.R.[164,175,176] Rarely, dosages of 1,200 mg/day of PTU or its equivalent may be required in patients with severe disease or storm.[192] Equipotent doses of methimazole (which is 10 times more potent than PTU on a mg-per-mg basis) can also be used. However, it is usually unnecessary to use >40 mg/day of methimazole to restore a euthyroid state.[164,175,176] Toxicity is also less common (see Case 52-15, Questions 10 and 11). True resistance to thioamides is rare; thus, most cases of unresponsiveness are caused by poor patient adherence, as in C.R.

C.R.'s adherence is also hindered by the frequency of PTU administration. The serum half-life of PTU is short (1.5 hours), but it is the intrathyroidal drug concentrations that should determine the dosing intervals because they are most clearly related to the drug's antithyroid effects.[176] PTU must be dosed every 6 to 8 hours initially, or as frequently as every 4 hours in cases of severe hyperthyroidism and thyroid storm. In contrast, methimazole has a serum half-life of 6 to 8 hours, remains in the thyroid for 20 hours, and has a duration of activity of up to 40 hours.[176,193]

Poor adherence is often difficult to ascertain and is more likely when multiple daily doses are required. The best option for C.R. is to change to 30 to 40 mg of methimazole, given once daily to improve adherence, or divided into two doses to decrease GI distress. After methimazole is given for 4 to 6 weeks to achieve euthyroidism, the daily dosage can be reduced gradually by 25% to 30% monthly to a dosage that maintains euthyroidism, usually 5 to 10 mg/day of methimazole. If C.R. remains hyperthyroid despite adequate doses of thioamides, then the most likely reason is non-adherence.

Monitoring Therapy

CASE 52-15, QUESTION 6: What additional objective baseline data should be obtained to monitor both the efficacy and toxicity of thioamides?

Before thioamides are administered, a baseline FT_4 and TSH should be obtained. A baseline white blood cell (WBC) count with differential can also help differentiate the leukopenia associated with hyperthyroidism from drug-induced leukopenia and/or agranulocytosis (see Case 52-15, Question 11). Baseline liver function tests can assist in the evaluation of thioamide-induced hepatotoxicity (see Case 52-15, Question 10). A repeat FT_4 and TSH should be obtained after 4 to 6 weeks on therapy and 4 to 6 weeks after any change in the dosing regimen. Once the patient is euthyroid on maintenance dosages, thyroid function tests can be obtained every 3 to 6 months.

Duration of Therapy

CASE 52-15, QUESTION 7: How long should C.R. be continued on thioamide treatment?

Traditionally, thioamide therapy is continued for 1 to 2 years despite the lack of data regarding the optimal treatment period.[164,175,176] The goal of treatment is to control the symptoms of Graves' disease until spontaneous remission occurs. Graves' disease remits spontaneously in about 30% to 50% of patients but relapse is high.[194] Because it is unknown when or if remission will occur, it is understandable why the optimal duration of therapy is unclear. Short-term therapy (i.e., <6 months) has been advocated to save time and money and improve adherence because earlier studies suggested remission rates comparable to a longer course of therapy.

However, short-term therapy is not recommended because longer follow-ups of patients receiving short-term therapy have noted poorer remission rates.[175,176]

Most data support a 12- to 18-month course of treatment to achieve remission rates of approximately 60%.[175,176,195,196] Two prospective randomized trials found that extending treatment from 6 to 18 months was beneficial but that 42 months of therapy was not significantly better than 18 months.[195,196] However, one retrospective study of patients treated for >12 months observed remission rates of only 17.5%.[197] These conflicting results underscore the fact that determining the optimal treatment period is confounded by the large variability that exists with regard to spontaneous remission. Nevertheless, treatment periods of 1 to 2 years are justifiable in adherent patients. Therapy can be reinstituted if hyperthyroidism reappears shortly after therapy is discontinued. Methimazole can also be continued indefinitely if there are no side effects, and treatment with either RAI or surgery is not desired. In C.R., this goal might not be achievable, given her history of non-adherence.

PRECAUTIONS

CASE 52-15, QUESTION 8: Can thioamide therapy affect any of C.R.'s preexisting medical conditions?

Thyrotoxicosis can activate or intensify diabetes, primarily by increasing the basal hepatic glucose production and the metabolism of insulin.[198] Therefore, effective therapy with thioamides may restore control of C.R.'s type 2 diabetes.

C.R.'s arthritis should not be affected, although thioamides have been associated with the development of lupus erythematosus (LE), lupus-like syndromes, and vasculitis.[176,199] These adverse drug reactions are rare; the incidence is <0.1%. Lupus-like syndromes include skin ulcers, splenomegaly, migratory polyarthritis, pleuritis and pericarditis, periarteritis, and renal abnormalities. Serologic abnormalities may also occur with these connective tissue disorders and include hyperglobulinemia, positive LE preparations, and positive antinuclear antibodies. Recovery occurs with adequate steroid therapy and withdrawal of the thioamides. Because cross-reaction between methimazole and PTU is likely to occur, patients exhibiting these reactions should be treated with surgery or RAI. C.R.'s treatment should be monitored with this lupus-like adverse effect in mind, but the occurrence of this syndrome is so uncommon that a trouble-free course of therapy can be anticipated.

ADJUNCTIVE THERAPY

CASE 52-15, QUESTION 9: What adjunctive therapy might help alleviate some of C.R.'s symptoms while awaiting the onset of thioamide's effects?

Iodides (see Case 52-15, Question 2) , β-adrenergic blocking agents without intrinsic sympathomimetic activity, or calcium channel blockers can be used acutely to ameliorate some of C.R.'s symptoms.[200,201] Because iodides were previously ineffective in C.R., a β-blocker should be tried.

β-Adrenergic blocking agents rapidly decrease the nervousness, palpitations, fatigue, weight loss, diaphoresis, heat intolerance, and tremor associated with thyrotoxicosis, probably because many of the signs and symptoms mimic sympathetic overactivity.[164,200] An increase in the number of β-adrenergic receptors rather than an elevation in catecholamine levels is probably responsible for this overactivity. Because the underlying disease process and thyroid hormone levels are not affected significantly by β-blockers, patients generally remain mildly symptomatic and fail to gain weight. For this reason, they should not be used as the sole treatment for thyrotoxicosis.

All β-blockers without intrinsic sympathetic activity (e.g., atenolol, metoprolol, propranolol) are effective in alleviating the hyperthyroid symptoms, but propranolol is the only β-blocker that significantly inhibits peripheral conversion of T_4 to T_3.[200] Thyroid function tests are generally not affected except for a mild decrease in the T_3 level.

In summary, β-blockers are (a) effective adjuncts in the management of thyroid storm, (b) useful to prepare patients for surgery, and (c) useful in the short-term management of thyrotoxicosis during pregnancy.[180,192,200] Surprisingly, propranolol also improves many of the neuromuscular manifestations of hyperthyroidism, including thyrotoxic periodic paralysis. Current guidelines recommend elderly patients, those with concomitant heart disease, and those with a resting heart rate over 90 beats/minute receive adjunctive therapy with β-blockers.[34]

Diltiazem or verapamil are effective alternatives when β-blockers are contraindicated.[201] Diltiazem 120 mg TID or QID can be tried. The dihydropyridine calcium channel blockers are unlikely to be effective.

Because of C.R.'s history of diabetes, the effects of β-adrenergic blocking drugs on patients with diabetes must be considered (see Chapter 53, Diabetes Mellitus). If β-blockers are instituted, a cardioselective β-blocker would be a better choice for patients

on therapy that can cause hypoglycemia. The appropriate dosage should be based on clinical and objective improvement of hyperthyroid symptoms, such as a reduction in heart rate. Metoprolol 25 to 50 mg BID can be started initially and the dosage titrated to maintain the heart rate at <90 beats/minute. Otherwise, diltiazem, verapamil, or a retrial of iodides is warranted.

ADVERSE EFFECTS

CASE 52-15, QUESTION 10: A pruritic area over the pretibial aspects of both legs as well as several maculopapular erythematous patches and abdominal tenderness were noticed during C.R.'s physical examination. Do these reactions require the discontinuation of her PTU?

Thioamide Rash

Although C.R. may be experiencing a drug rash from PTU, pretibial myxedema or the dermopathy of Graves' disease may also be possibilities because of the location of the pruritic area. About 4% of patients with Graves' disease who exhibit infiltrative exophthalmos also have dermatologic changes. The skin is thickened, erythematous, and non-pitting because of mucopolysaccharide infiltration and accentuation of hair follicles. Pruritus or pain may be present. Treatment includes topical corticosteroids, control of the Graves' disease, and reassurance.

Thioamides can produce a maculopapular pruritic rash in 5% to 6% of treated patients.[176] The rash can occur at any time but is more common early in therapy. If the rash is mild, drug therapy can be continued while the patient's symptoms are treated with an antihistamine and a topical steroid; such rashes generally subside spontaneously. Alternatively, another thioamide can be substituted because cross-sensitivity to this side effect is uncommon. Thioamides should be stopped if the rash is urticarial in nature or associated with systemic manifestations (e.g., fever, arthralgias).

Hepatitis

C.R.'s symptoms of nausea, vomiting, diarrhea, fatigue, and abdominal tenderness require further evaluation. Her symptoms could be consistent with mild GI side effects from her PTU therapy, impending thyroid storm from non-adherence (see Case 52-22, Question 1) or more seriously, PTU-induced hepatitis. PTU has been associated with 0.1% severe hepatotoxicity, leading to liver transplants and fatalities primarily in children.[30,169,202,203] Although usually hepatocellular in nature, cholestasis, hepatic necrosis, and fulminant hepatic failures have been reported.[168,170,176] Transient elevations in transaminases occur in approximately 30% of asymptomatic patients within the first 2 months of PTU therapy and may not require drug discontinuation.[168] Liver enzymes usually normalize within 3 months of reducing the PTU to maintenance dosages despite drug continuation. However, PTU should be stopped immediately in patients with clinical symptoms of hepatitis to ensure complete recovery. The mechanism of PTU-induced hepatotoxicity appears to be autoimmune because circulating autoantibodies and in vitro peripheral lymphocyte sensitization to PTU have been detected.[170] Overt hepatitis typically occurs during the first 2 months of PTU therapy and is not dose related. In contrast, methimazole rarely produces a cholestatic jaundice picture that might be more common in older patients and in those receiving higher dosages (i.e., >40 mg/day).[171] In patients with thioamide-induced hepatitis, changing to the alternative thioamide is not recommended because fatalities have been reported on rechallenge. In such patients, either radioactive therapy or surgery should be used.

In C.R., PTU should be stopped while awaiting results of thyroid function tests, transaminases, and bilirubin. Routine monitoring of liver function tests is not recommended during thioamide therapy because patients can be asymptomatic. However, routine monitoring might be reasonable in patients with a history of liver disease and risk factors for hepatitis (e.g., alcohol use). All patients receiving thioamides should be questioned closely during the first 2 months of therapy for symptoms of hepatitis, and hepatic function tests should be obtained if appropriate.

Agranulocytosis

CASE 52-15, QUESTION 11: Assess C.R.'s complaints of sore throat and cough.

C.R.'s complaints should not be dismissed casually because they might indicate PTU-induced agranulocytosis. Agranulocytosis ($<500/\text{mm}^3$ of neutrophils) is the most severe adverse hematologic reaction associated with the thioamides and should be considered strongly in C.R.[176,204] In contrast, drug-induced leukopenia is usually transient, is not associated with impending agranulocytosis, and is not an indication to discontinue thioamide therapy. An accurate history should be obtained from C.R. The clinician should be particularly alert for a temperature of 101°F for 2 or more days, malaise, or other flu-like findings that appeared temporally with her sore throat. If subjective or objective data are consistent with agranulocytosis, the PTU should be discontinued immediately until the results of a repeat WBC count with a differential are obtained. Traditionally, routine serial determinations of WBC counts are not recommended for monitoring the development of agranulocytosis because the onset is so abrupt. Instead, patients should be instructed to immediately report rash, fever, sore throat, or any flu-like symptoms. However, one study suggested that weekly monitoring of the WBC count with a differential during the first 3 months of antithyroid therapy might identify asymptomatic patients with agranulocytosis before infection occurs.[204]

The prevalence of agranulocytosis is about 0.5% but ranges from 0.5% to 6%.[176,204] The risk factors for agranulocytosis are unknown. There is no predilection for either gender, and the reaction may be idiosyncratic or dose related. Some reports suggest that patients older than 40 years or those taking high dosages of methimazole (e.g., >40 mg/day) might be more susceptible than those on any dosage of PTU. Although controversial, patients receiving low dosages of methimazole (e.g., <40 mg/day) might be at less risk than those receiving high or conventional dosages of PTU.[176,204]

Agranulocytosis typically develops within the first 3 months of treatment, although it can occur at any time and as late as 12 months after starting thioamide therapy.[176] A delayed reaction is more common with methimazole therapy than with PTU. In 55 patients who developed agranulocytosis while taking thioamides, the duration of PTU therapy (17.7 ± 9.7 days) was significantly shorter than for methimazole therapy

(36.9 ± 14.5 days).[204] The mechanism of thioamide-induced agranulocytosis is unknown. Both allergic- (idiosyncratic) and toxic-type (dose-related) reactions have been suggested. An autoimmune reaction with circulating antineutrophil antibodies and lymphocyte sensitization to antithyroid drugs has been demonstrated.[205] Death usually results from overwhelming infection.

If agranulocytosis is diagnosed, the drug should be discontinued, the patient monitored for signs of infection, and antibiotics instituted if necessary. Granulocyte colony-stimulating factors may shorten the recovery period.[176,206] If the patient recovers, granulocytes begin to reappear in the periphery within a few days to 3 weeks; a normal granulocyte count occurs shortly thereafter.[204,206]

Although some cases of granulocytopenia have resolved with substitution or continuation of thioamides, the risks of drug rechallenge clearly outweigh the benefits, and other treatments

---

should be instituted. Changing to an alternative thioamide should also be avoided because of possible cross-sensitivity between these agents.[176]

In summary, all patients receiving thioamide therapy should be well educated regarding the signs and symptoms of agranulocytosis. If these symptoms develop, they should be advised to contact their physician or pharmacist. If they cannot reach their own physician, patients should inform the emergency physician that they are taking thioamides, and a WBC count with differential should be obtained. Routine monitoring of a WBC and differential is not recommended until further studies justify that it is indicated and cost-effective.

PREOPERATIVE PREPARATION

CASE 52-15, QUESTION 12: C.R.'s PTU is discontinued because she developed agranulocytosis and hepatitis, and surgery is scheduled when her granulocyte level returns to normal. What thyroid preparation is needed for C.R. before thyroidectomy? What postoperative complications are associated with thyroidectomy?

C.R. should be in a euthyroid state at the time of surgery to avoid precipitation of thyroid storm and morbidity. Generally, iodides (see Case 52-15, Question 2), thioamides, or propranolol can be used.[173,192,200] The combination of iodides and propranolol is more effective than either used alone. Propranolol used alone has been associated with thyroid crisis postoperatively and may be less effective than iodides in decreasing gland friability and vascularity.[200]

Because C.R. received only 1 week of thioamide therapy, it is likely that her gland still contains large stores of hormone; therefore, pretreatment is necessary.

In addition to the risks of anesthesia and surgery, postoperative complications include hypoparathyroidism, adhesions, laryngeal nerve damage, bleeding, infection, and poor wound healing. However, complications can be minimized if the surgery is performed by experienced surgeons.[180–183,207] Complications are also higher if a total rather than a subtotal thyroidectomy is performed, but there is a lower risk of recurrent hyperthyroidism. Development of hypothyroidism, especially subclinical hypothyroidism, is greatest during the first year after surgery, with an insidious rise in incidence over the next 10 years. The incidence of permanent hypothyroidism varies from 6% to 75% and is related inversely to the amount of remnant tissue left behind.[180–183,207] Thyroid function tests should be monitored annually after surgery. When total thyroidectomy is performed, postoperative L-thyroxine should be initiated at a dose of 1.7 mcg/kg/day.[34] Inadvertent parathyroidectomy can result in life-threatening hypocalcemia. Patients receiving total thyroidectomy should have postoperative measurement of serum calcium and/or intact parathyroid hormone concentrations.[34]

REMISSION RATES WITH THIOAMIDES

CASE 52-16

QUESTION 1: B.D., a 30-year-old woman, has been maintained on methimazole 5 mg daily for >2 years. Her methimazole has been discontinued twice in the past, and each time her hyperthyroidism recurred. She refuses either surgery or RAI therapy. Although she is clinically euthyroid on methimazole, her gland is larger than her usual size and has never decreased with therapy. Recent laboratory tests showed an FT_4 of 1 ng/dL (normal, 0.8–1.4) and a TSH level of 6.5 microunits/mL (normal, 0.45–4.1). What is responsible for the enlarging gland? What subjective or objective data in B.D. would influence her remission rate and justify a longer course of thioamide therapy? Would the addition of T_4 be helpful?

The high TSH level suggests that TSH stimulation caused by excessive suppression of hormone synthesis by methimazole is contributing to the enlarging thyroid gland. The easiest solution to this problem is to decrease the maintenance dose of methimazole to 2.5 mg daily to normalize the TSH value and minimize gland stimulation.

Long-term remission rates achieved with the thioamides are disappointing. Remission rates within 6 years after discontinuing therapy average 50% (range, 14%–75%),[175,176,195–197] although relapse rates are as high as 80%. The rate of permanent remission is usually <25% if the follow-up period is long enough.[175,176,208] Why some patients remain in remission while others relapse once thioamides are discontinued is unclear, although patients who remain euthyroid for >10 to 15 years after discontinuing therapy probably do so because of disease progression to Hashimoto's thyroiditis rather than as a direct result of treatment.[164] In other words, the natural course of Graves' hyperthyroidism might be eventual hypothyroidism regardless of the treatment modality used. Several factors have a limited role in predicting relapse and remission and have been used to guide therapy.

A longer duration of thioamide treatment (see Case 52-15, Question 7) improves the remission rate by changing the basic underlying abnormality of Graves' disease.[175,195–197] Numerous studies show that titers of antithyroid receptor (TSI) and antimicrosomal antibodies fall during thioamide therapy but are unchanged during therapy with placebo or β-blockers.[175,176,196,209] Patients with low or undetectable TSI titers at the end of 12 to 24 months of thioamide therapy had a 45% chance of remission compared to <10% chance of remission for those with higher titers within 1 to 5 years after completing therapy.[208–211] The best response was obtained in those with smaller goiters, less severe disease, and nonsmokers. A higher thioamide dose did not improve the remission rate but resulted in more toxicity, including agranulocytosis, arthralgias, dermatitis, gastritis, and hepatotoxicity.[175,195,208]

Certain clinical features have been associated with a greater chance of disease remission and might help clinicians identify patients who deserve a longer thioamide trial before changing to RAI or surgery. These clinical features include smaller goiter, mild symptoms of short duration, a reduction in goiter size during treatment, nonsmokers, absence of ophthalmopathy, and undetectable or low TSI levels.[176,208,209] Smokers should be advised to discontinue smoking to increase the chance of remission (see Chapter 91, Tobacco Use and Dependence).[212]

In a preliminary study, the addition of L-thyroxine to maintenance doses of thioamides for 1 year, followed by an additional year of L-thyroxine alone, significantly reduced the risk of relapse after stopping thioamides.[211] Those receiving the T_4-methimazole combination experienced significant reductions in TSH receptor antibody titers compared to those taking methimazole alone. At 3 years, the combination-treated patients had a lower rate of recurrence after stopping therapy (1.7%) than those receiving methimazole alone (recurrence rate, 34.7%). Unfortunately, several prospective studies evaluating the addition of T_4 to thioamides have not validated these initial favorable results.[208,210,213,214] Support for this therapeutic approach has waned, and the addition of T_4 to existing thioamide therapy is not recommended.

B.D.'s large goiter reduces her chance of remission with longer therapy. Although thioamide therapy can be continued indefinitely if well tolerated, surgery or RAI therapy should seriously be considered for B.D., who already has received methimazole for >2 years. Alternative therapy is especially crucial if she plans to become pregnant within the next few years (see Case 52-18).

Subclinical Hyperthyroidism

CASE 52-17

QUESTION 1: J.C. is a 68-year-old male who is found to have a TSH level of 0.15 microunits/mL (normal, 0.45–4.1) with normal FT_4 and FT_3 hormone levels on routine blood tests. He is otherwise healthy and denies any symptoms of thyroid dysfunction. On physical exam, his thyroid gland is normal. He denies any family history of thyroid disease and is taking no medications. How should these tests be interpreted? How should J.C. be managed?

J.C.'s laboratory findings of a suppressed TSH value below the limits of normal and normal free thyroid hormone levels are consistent with subclinical hyperthyroidism (SHyper).[87–89] Other unlikely causes of a suppressed TSH in J.C. include medications (e.g., metformin, bexarotene, glucocorticoids) (Table 52-1), pituitary hypothyroidism, and non-thyroidal illness (see Case 52-1, Questions 1 and 2).[10,60] A suppressed TSH may also be a normal finding in healthy elderly patients.

The dangers of SHyper are similar to those of overt hyperthyroidism and include cardiac findings (e.g., atrial and ventricular premature beats, atrial fibrillation [AF], left ventricular hypertrophy, diastolic dysfunction), loss of bone mass, higher fracture rates, especially in postmenopausal women, and if present, subtle symptoms of hyperthyroidism.[85–89] In elderly patients, hyperthyroid symptoms, even if overtly hyperthyroid, may be "apathetic" unapparent because of impaired sympathetic nervous system responsiveness. A significant relationship between atrial fibrillation and degree of SHyper is clear, whereas an association with increased atherosclerotic heart disease or mortality is weak.[158] The relative risk of AF in SHyper may be as high as 5.2 and increased by older age, male gender, higher FT_4 levels, and degree of TSH suppression. In two cohorts followed for 10 to 13 years, the relative risk of atrial fibrillation ranged from 1.6 to 3.1, depending on the degree of TSH suppression.[158,215] The likelihood a patient with endogenous SHyper will progress to overt hyperthyroidism is not clear. Patients may spontaneously revert to euthyroidism, progress to hyperthyroidism or continue with SHyper. Individuals with undetectable TSH concentrations appear most likely to progress, and overall the rate of progression to overt disease is 1% to 5% annually. [88] A study of 2,024 patients with 7-year follow-up of SHyper importantly found 36% reverted back to normal within 7 years, especially those with TSH levels between 0.1 and 0.4 microunits/mL.[216]

The management of subclinical hyperthyroidism is controversial, especially in asymptomatic patients because of limited treatment outcomes evidence.[87–89] Current guidelines recommend treatment of subclinical hyperthyroidism (TSH levels <0.1 microunits/mL) in patients >65 years, postmenopausal woman not taking antiresorptive therapy (see Chapter 110, Osteoporosis), and those with cardiac disease and osteoporosis.[34,87,88] For patients with TSH levels of 0.1 to 0.45 microunits/mL, treatment of patients >65 years of age and those with cardiovascular disease or hyperthyroid symptoms can be considered.[34] A recent review recommends RAI or thioamide therapy only if the TSH level is <0.1 microunits/mL in postmenopausal women, in those 60 years or older, and in patients with a history of heart disease, osteoporosis, or hyperthyroid symptoms.[89] For patients with TSH levels of 0.1 to 0.4 microunits/mL, treatment can be considered if they are in the aforementioned groups; otherwise, therapy is not recommended because TSH normalization may occur.

In J.C., his thyroid function tests should be repeated. An RAIU and scan should be obtained to detect any hyperactive areas or nodules that might be responsible for the suppressed TSH. Because J.C. is generally healthy, treatment can be considered if there are concerns about cardiac disease or bone loss; otherwise, no therapy is reasonable based on the available evidence. Close monitoring of thyroid function tests is recommended every 6 months to 1 year. If hyperthyroid symptoms or changes in cardiac or bone function occur, then RAI therapy is recommended.

HYPERTHYROIDISM IN PREGNANCY

CASE 52-18

QUESTION 1: N.N., a 32-year-old woman who is 3 months pregnant, is referred for management of her Graves' disease. What are the therapeutic ramifications of managing thyrotoxicosis during pregnancy?

Hyperthyroidism develops in 0.02% to 1.4% of pregnant women and often precedes conception.[217] Symptoms of thyrotoxicosis are typically ameliorated during the second and third trimesters and exacerbated early in the postpartum period. Treatment is crucial to prevent damage to the fetus and to maintain the pregnancy. RAI, chronic iodide therapy, and iodine-containing compounds are contraindicated during pregnancy because they will cross the placenta to produce fetal goiter and athyreosis.[217–219] As little as 12 mg/day of iodide has produced neonatal goiter and death. The long-term use of β-adrenergic blockers should also be avoided because it is associated with fetal respiratory depression, a small placenta, intrauterine growth retardation, impaired response to anoxia, and postnatal bradycardia and hypoglycemia.[217,218] However, if rapid control of hyperthyroidism is required, short-term use (<1–4 weeks) of propranolol is safe.[102,105,217–219] Iodide use in pregnancy should be limited to transient preoperative use prior to thyroidectomy or in the management of thyroid storm.[105,220]

Either surgery or thioamide is the treatment of choice for pregnant hyperthyroid patient. Surgery is safe during the second trimester with adequate preoperative preparation. During other trimesters, thioamides are preferred because surgery can precipitate spontaneous abortion. PTU is preferable during the first trimester because of rare reports of teratogenicity from methimazole, but methimazole is preferred thereafter to reduce the risks of PTU-associated hepatitis. Both thioamides are equally effacious,[221] demonstrate similar placental crossing properties,[222] and produce similar thyroid hormone concentrations in fetal umbilical cord blood samples.[223] Methimazole has been associated with anecdotal reports of congenital scalp defects (e.g., aplasia cutis) and an embryopathy syndrome (esophageal and choanal atresia).[224–227] However, the risks of reversible aplasia cutis were not greater in women receiving methimazole (e.g., 2.7%) compared to PTU (e.g., 3%) or hyperthyroid controls (e.g., 6%).[221,224,225] Therefore, methimazole can be considered throughout pregnancy if there is intolerance or non-adherence to PTU[217,218,221] (see Chapter 49, Obstetric Drug Therapy).

Fetal hypothyroidism and goiter can develop when large doses of thioamides are administered to the mother, even if the mother is still hyperthyroid.[217,218] Therefore, to avoid goiter and suppression of the fetal thyroid gland, which begins to function at about 12 to 14 weeks of gestation, the lowest effective thioamide dose should be given. Normal FT_4 levels occur in >90% of neonates when maternal FT_4 is maintained in the upper third of the normal range (1.5–1.9 ng/L).[105,220] Conversely, over 30% of neonates exhibit a low FT_4 when maternal levels are maintained in the lower two-thirds of the normal range.[105] Control of maternal hyperthyroidism increases the risk of fetal hypothyroidism. Start PTU (e.g., maximum of 300 mg/day in three divided doses) or methimazole (e.g., maximum of 20–30 mg given once daily) until control is achieved, then taper PTU to 50–150 mg/day, and after the first trimester, change to 5 to 15 mg/day of methimazole for the remainder of the pregnancy. In many patients, remission

---

of Graves' disease occurs during pregnancy, and some patients can discontinue thioamides in the second half of pregnancy.[217] Measurement of TRAb levels between weeks 22 and 26 of gestation can be useful, because disappearance of TRAb indicates that thioamide therapy may no longer be necessary.[34] Such modest doses of thioamides provide satisfactory control of maternal hyperthyroidism and should not cause clinically evident neonatal thyroid dysfunction. Patients requiring more than the maximum recommended thioamide dosages for control may need to consider the possibility of surgery in the second trimester.

Nevertheless, a small but significant reduction in neonatal serum T_4 occurs even when small (100–200 mg) doses of PTU are administered during pregnancy to mothers with Graves' disease.[217,218,226] It is unclear whether this mild, transient reduction in serum T_4 causes long-term impairment of mental development or is otherwise detrimental to the newborn. To date, no significant differences in intellectual development have been noted between children exposed to PTU or methimazole in utero and their unexposed siblings.[228–230] However, children exposed in utero to >300 mg/day of PTU had lower IQs.[228,229]

Although transient fetal or neonatal hypothyroidism does not appear to be a major threat to the baby, it is advisable to maintain the mother in a mildly hyperthyroid state.[217,218] Mild maternal hyperthyroidism appears to be well tolerated, but maternal hypothyroidism is poorly tolerated by both the mother and the fetus (see Case 52-8, Question 1). T_4 levels should be maintained in the upper third of the normal range to decrease the risk of fetal hypothyroidism because normal thyroid function tests are suggestive of hypothyroidism during pregnancy (high TBG and TBPA levels). The goal of therapy is a suppressed maternal TSH level (0.1–0.4 microunits/mL) because complete correction maternal hyperthyroidism increases the risk of fetal hypothyroidism.[34,102]

It is not rational to add thyroid hormone to the mother's regimen to prevent fetal goiter or hypothyroidism because thyroid hormones do not reach the fetal circulation. Thyroid supplementation only complicates the treatment of maternal hyperthyroidism by increasing thioamide requirements, which can further compromise fetal thyroid hormone production.[217] If the mother has not been thyrotoxic throughout pregnancy, a normal infant can be expected. All pregnant patients with a history of or active Graves' disease should be screened with a TSI during pregnancy to assess the risk of neonatal hyperthyroidism.[217] Neonatal Graves' disease occurs in 1% to 5% of infants born to mothers with the disease; therefore, all newborns should be evaluated for the condition.[105,220] Lastly, both thioamides can be safely used in the lactating mother if the maximal dose of methimazole does not exceed 10 to 20 mg daily or less preferably, if PTU does not exceed 200 mg/day (up to 750 mg/day in one report).[231,232] Propranolol and iodides are secreted in breast milk and should be avoided (see Chapter 49, Obstetric Drug Therapy).

Treatment with Radioactive Iodine

PRETREATMENT

CASE 52-19

QUESTION 1: B.J., a 35-year-old woman, has newly diagnosed Graves' disease complicated by CHF and angina. After a few days of treatment with methimazole 30 mg daily and Lugol's solution, 5 drops/day, B.J. received RAI therapy. Six months later, she is still symptomatic. Evaluate the influence of B.J.'s pretreatment therapy on the efficacy of her RAI therapy.

Older or debilitated patients with severe hyperthyroidism and/or concomitant cardiac disease should receive antithyroid pretreatment before RAI therapy to deplete stored thyroid hormone and minimize post-RAI hyperthyroidism (occurring in the first 10 days after ^{131}I administration) and thyroid storm caused by leakage of hormones from the damaged thyroid gland.[176,192,233] Other hyperthyroid patients can receive RAI safely without pre-therapy.

Lugol's solution or other iodides should not be given before RAI because iodides decrease the gland's uptake of RAI and its effectiveness. This effect of iodides persists for several weeks. Iodides can be given 1 to 7 days after RAI treatment if it is needed to rapidly control symptoms of hyperthyroidism.

Prior to RAI, thioamides achieve a euthyroid state, but pretreatment may lower the cure rate and increase the need for subsequent RAI.[176,184,234] A meta-analysis of 14 trials found that use of thioamides (e.g., PTU, methimazole, carbimazole) before and after RAI was associated with an increased risk of treatment failure (relative risk of 1.28; 95% CI, 1.07–1.52) and a 32% reduced risk of hypothyroidism regardless of the thioamide used.[184] To facilitate optimal uptake and retention of ^{131}RAI by the gland, thioamides should be stopped at least 2 to 3 days, before RAI administration.[234–236] If necessary, thioamides can be restarted 3 to 7 days after RAI administration without impairing its efficacy. β-Adrenergic blocking agents can be used before, during, and after RAI therapy without interfering with its uptake.

B.J. remains symptomatic because methimazole and iodides decreased RAI's efficacy. Propranolol should be given to B.J. before RAI therapy to relieve hyperthyroid symptoms because only a short course of thioamide was given. Iodides might be preferable to propranolol following RAI therapy if B.J.'s CHF worsens. For subsequent RAI doses, methimazole pretreatment should be stopped 2 to 3 days before RAI, thereby allowing a shorter duration of hyperthyroidism.

ONSET OF EFFECTS

CASE 52-19, QUESTION 2: B.J. is still symptomatic 2 weeks after a second dose of RAI. When can she expect to experience the therapeutic effects of RAI therapy? What educational precautions about radiation safety should B.J. receive?

Although some benefits from RAI therapy are evident within 1 month, a period of 6 to 18 weeks is generally required for maximal effects.[164,184,233] Euthyroidism or, more commonly, hypothyroidism occurs in approximately 80% to 90% of patients treated with a single nonablative dose of RAI; the remaining 10% to 20% become euthyroid or hypothyroid after two or more doses. This slow onset is a disadvantage, but symptomatic control can be obtained quickly by administration of a β-adrenergic blocking agent, or iodides starting 1 to 14 days after the ^{131}I dose. Iodides are less preferable if a second dose of RAI is necessary. Thioamides can also be given, although their therapeutic effects are delayed for 3 to 4 weeks.

At least 3 months should elapse before a second dose of RAI is administered, and most recommend waiting 6 months before repeating RAI, unless the patient remains severely thyrotoxic. It is inadvisable to give a second dose before the major effects of the first dose have become apparent. Although the use of iodides before RAI in B.J. may have decreased the amount of ^{131}I retained by her thyroid, it is still advisable to wait at least 3 months before a second dose is given.

Safety precautions are not universal and vary across the United States depending on the dose of RAI administered.[184] B.J. should avoid close contact (e.g. 6 ft) with children for 5 days, with pregnant women for 10 days, and intimate contact with body fluids for 5 days. B.J. should avoid airplane travels, public transportation, and work if contact with others during these activities last more than 2 hours. Other recommendations include sole use of bathroom facilities; sitting while urinating to avoid splashing and to flush the toilet twice with the lid down.

IATROGENIC HYPOTHYROIDISM

CASE 52-20

QUESTION 1: S.D., a 54-year-old woman, returns to the thyroid clinic after being lost to follow-up for 6 months. She initially received RAI 3 years ago but required a repeat dose of RAI 1 year ago. She has no other medical problems and is not taking any medications. She is a mildly obese, puffy-faced woman wearing several layers of clothing who complains of fatigue and lack of energy. Her reflexes are delayed, and her skin is cool and dry. What is a likely explanation for her symptoms?

S.D.'s clinical presentation and history are compatible with hypothyroidism secondary to RAI therapy. A FT_4 and a TSH level would confirm this diagnosis. Iatrogenic hypothyroidism is the major complication of RAI therapy, although transient hypothyroidism can occur in the first 3 to 6 weeks after therapy.[164] The incidence of iatrogenic myxedema is often reported as 7% to 8%, but it increases at a constant rate of 2.5% per year. The reported prevalence of this complication ranges from 26% to 70% after 1 to 14 years.[233]

The best predictor of eventual hypothyroidism is the total dose of RAI administered. Prevention of iatrogenic hypothyroidism is directed toward calculation of a dose that will produce neither recurrent hyperthyroidism nor hypothyroidism. Unfortunately, when lower doses of RAI were used to avoid hypothyroidism, the cure rate was reduced but the incidence of hypothyroidism was unaffected. Thus, the appearance of iatrogenic hypothyroidism may be inevitable with time. However, hypothyroidism is managed easily and is an acceptable therapeutic end point. Because hypothyroidism after RAI therapy is latent and often insidious, patients should be informed of this and monitored closely at monthly intervals for subsequent hypothyroidism. Awareness of a transient hypothyroidism soon after RAI therapy should minimize the institution of unnecessary hormone replacement.

Ophthalmopathy

CLINICAL PRESENTATION

CASE 52-21

QUESTION 1: H.R., a 50-year-old man, first developed "large eyes with stare" (Figure 52-3), weakness, diaphoresis, and thyroid enlargement when he was diagnosed with Graves' disease. RAI therapy caused some worsening of his eye symptoms. Although he is clinically euthyroid, physical examination reveals severe bilateral conjunctival edema and injection, proptosis of the right eye, incomplete lid closure, and decreased visual acuity. He complains of photophobia, tearing, and extreme irritation, which is worse after smoking cigarettes. His other medical problems include type 2 diabetes treated with metformin and pioglitazone. What is the association of H.R.'s ocular changes with Graves' disease?

H.R. presents with symptoms consistent with the infiltrative ophthalmopathy of Graves' disease.[237–239] The eye signs of Graves' disease are the most striking abnormality of this disorder. Rarely, ophthalmopathy can occur without any evidence of hyperthyroidism. Fortunately, severe ophthalmopathy occurs in only 3% to 5% of patients, while 25% to 50% have some eye findings. Eye disease is more severe in older patients and in men than women. Smokers often have higher levels of TSI and more severe ophthalmopathy.[212,238,240]

It is unknown why the eye and its muscles are attacked in Graves' disease but is likely related to the presence of TSH receptor antibodies found in patients with ophthalmopathy.[239] Histologic examination reveals lymphocytic infiltration, increased mucopolysaccharides, fat (because of increased adipogenesis and glycosaminoglycans), and water in all retrobulbar tissue. Ocular symptoms include edema, chemosis, excessive lacrimation, photophobia, corneal protrusion (proptosis), scarring, ulceration, extraocular muscle paralysis with loss of eye movements, and blindness from retinal and optic nerve damage.

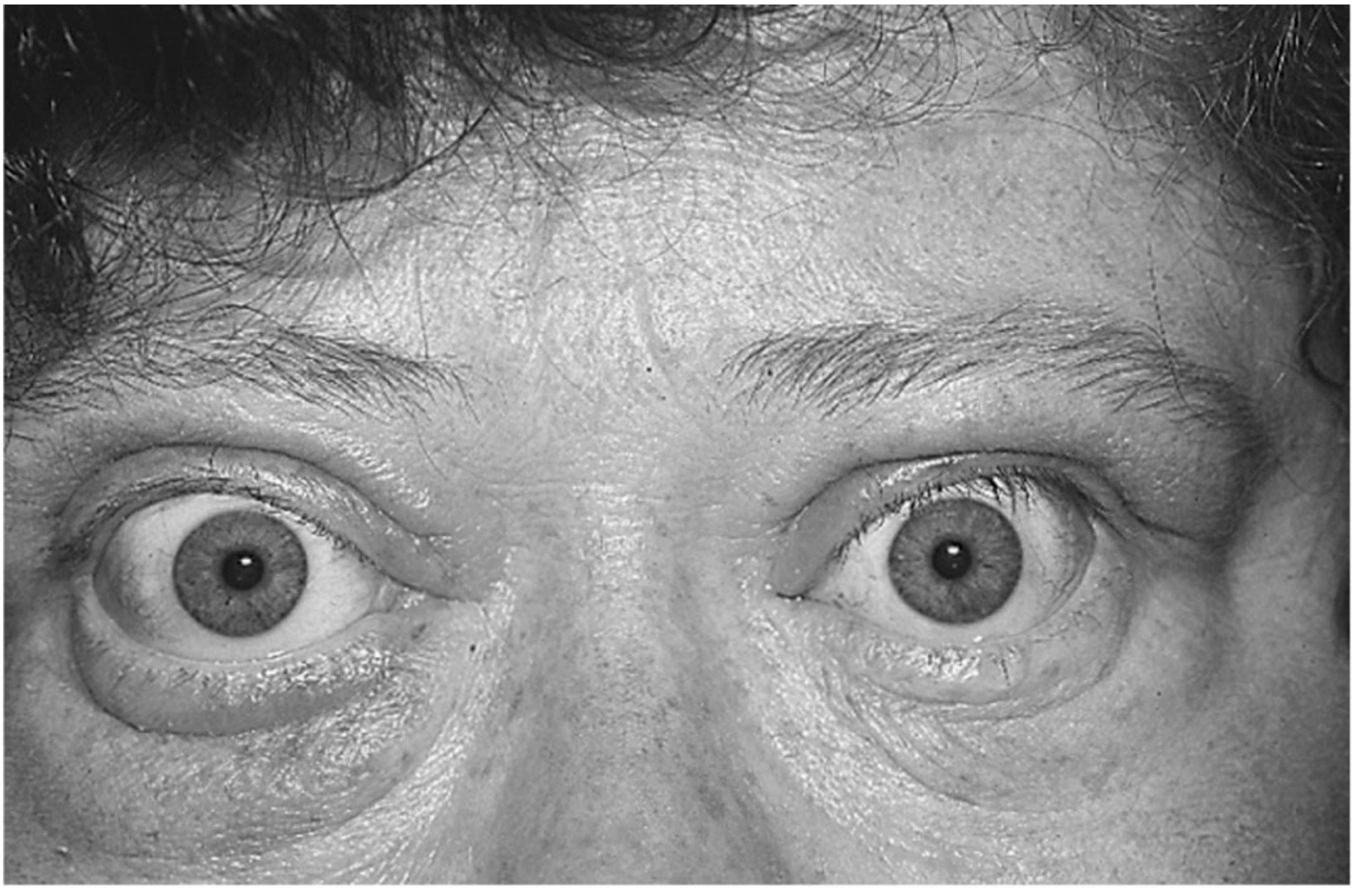

Figure 52-3 Graves' disease ophthalmopathy. (Reprinted with permission from Goodheart HP. Photoguide of Common Skin Disorders. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

The eye involvement can occur at any time and is usually bilateral. The ocular symptoms usually subside or remain stable once the patient is euthyroid; however, some cases will progress during the euthyroid period or following RAI treatment of the hyperthyroidism (see Case 52-21, Question 2). Pioglitazone has been associated with a 1 to 2 mm increase in eye protrusion by stimulating adipogenesis and increasing retrobulbar fat production.[241] While eye changes were more common in people with a history of thyroid disorders, the overall incidence of eye changes associated with pioglitazone is unknown.[241]

MANAGEMENT OF EYE SYMPTOMS

CASE 52-21, QUESTION 2: Was previous treatment of H.R.'s hyperthyroidism appropriate? How should his current ocular symptoms be managed?

The optimal treatment of hyperthyroidism and its effect on the course of ophthalmopathy remain controversial.[237,238,242] Thioamides might improve eye symptoms through an immunosuppressive mechanism of action and control of the hyperthyroidism or exert a neutral effect.[237] Many clinicians believe that RAI ablation or surgical removal is preferable because it removes the antigen source and prevents progression of the ophthalmopathy.[180,237] However, several studies have confirmed development or worsening of eye symptoms immediately after RAI therapy.[240,242] Concomitant use of 0.4 to 0.5 mg/kg of prednisone begun 1 to 3 days post-RAI continued for one month and tapered over 2 months may be used in patients with mild active eye disease to prevent progression of eye symptoms.[34,240,242] A recent study showed lower dose, shorter duration prednisone therapy (0.2 mg/kg/day for 6 weeks) to conventional doses as effective as conventionally used doses.[243] After 6 months there was no difference in clinical activity score, exophthalmos, or lid retraction. Patients with active moderate-to-severe or sight threatening ophthalmopathy at the time of treatment should be treated with surgery or thioamides instead of RAI.[34] Regardless of the treatment used, control of the hyperthyroidism often improves most eye findings, except for proptosis.

In H.R., prednisone 40 to 60 mg/day should have been started after his RAI treatment and continued for 2 to 3 months

---

until the eye symptoms improved. Because the pathophysiology of the ophthalmopathy is unclear, treatment is limited to symptomatic and empiric measures once the patient is euthyroid.[237,238] H.R. should also be encouraged to stop smoking to prevent progression of the ophthalmopathy.[212] His pioglitazone should be discontinued, in case this is contributing to his ophthalmopathy.

Because periorbital edema and chemosis are worse in the morning after being in the horizontal position, elevating the head of the bed, diuretics, and restricting salt intake may be helpful. Protective glasses can relieve photophobia and external irritation. Topical corticosteroid drops are effective in decreasing local irritation, but they should be used cautiously because they increase the risk of infection. Ocular irritants such as smoke and dust should be avoided. Bothersome symptoms (e.g., dry eye, redness, tearing) caused by eyelid retraction can be relieved by artificial tears and lubricants.[237] Incomplete lid closure predisposes to corneal scarring and ulceration, so lubricant eyedrops should be applied several times daily and at night to keep the bulbs moist. Taping the eyelids shut at night prevents drying and scarring. Lateral surgical closure of the lids (tarsorrhaphy) may be required to improve lid closure.

With severe and progressive ophthalmopathy, an aggressive approach is necessary. Systemic corticosteroids can produce either dramatic or marginal results in the emergency treatment of progressive exophthalmos associated with decreasing visual acuity. Prednisone at dosages of 35 to 80 mg/day is often effective, although dosages as high as 100 to 140 mg/day may be necessary.[237,238] Pain, irritation, tearing, and other subjective complaints often respond within 24 hours of administration. Therapy for about 3 months is necessary to improve eye muscle and optic nerve function disturbances. Initial large doses should be tapered rapidly once the desired response is obtained to minimize adverse effects. Subconjunctival and retrobulbar injections of steroids are not as effective.

Orbital x-ray therapy also relieves congestive and inflammatory symptoms.[237] The combination of orbital irradiation and systemic steroids may be required to achieve maximal benefits. Plasmapheresis and immunosuppressive agents, such as cyclophosphamide, azathioprine, cyclosporine, and methotrexate, combined with steroids have also been used with limited success. Future investigations are focusing on anti-TNF and anti-interleukin receptor antibodies agents that may neutralize some of the inflammatory reactions in the eye.[237,239]

When the previous measures and thyroid ablation fail to arrest the progression of visual loss and exophthalmos, then surgical orbital decompression should be considered.

Thyroid Storm

CLINICAL PRESENTATION

CASE 52-22

QUESTION 1: H.L., a 48-year-old woman, is admitted to the hospital with a 3-week history of fatigue, weakness, dyspnea on exertion, SOB, palpitations, and inability to keep food and liquids down. One year before admission, she began noticing a preference for cold weather and an increase in nervousness and emotional liability. After her husband died a few days ago, she experienced increased nausea and vomiting, irritability, insomnia, tremor, and a 104°F fever, which she attributed to an upper respiratory tract infection. She denies taking any current medications. Her laboratory data obtained on admission included an FT_4 of 4.65 ng/dL (normal, 0.8–1.4) and an undetectable TSH level. Assess H.L.'s subjective and objective data.

The presentation is consistent with thyroid storm, a life-threatening medical emergency that might have been precipitated by the stress associated with the death of her husband. The clinical manifestations of thyroid storm[192] include the acute onset of high fever, tachycardia, and tachypnea, and involvement of the following organ systems: cardiovascular (tachycardia, pulmonary edema, hypertension, shock), CNS (tremor, emotional liability, confusion, psychosis, apathy, stupor, coma), and GI (diarrhea, abdominal pain, nausea and vomiting, liver enlargement, jaundice, nonspecific elevations of bilirubin and prothrombin time). Hyperglycemia is also a common clinical finding in thyroid storm.

Thyroid storm develops in about 2% to 8% of hyperthyroid patients. The pathogenesis of thyroid storm is not well understood, but the condition can be described as an "exaggerated" or decompensated form of thyrotoxicosis. The term decompensated implies failure of body systems to adequately resist the effects of thyrotoxicosis. It is not attributed solely to the release of massive quantities of hormones, which can occur after surgery or RAI therapy. Catecholamines also play an important role; the increased quantities of thyroid hormone in conjunction with increased sympathetic and adrenal output contribute to many of the manifestations of thyroid storm. Although thyroid hormones exert an independent effect, many of the symptoms of hyperthyroidism are ameliorated by catecholamine-blocking agents such as β-blockers and calcium channel blockers (e.g., diltiazem, verapamil).

TREATMENT

CASE 52-22, QUESTION 2: What treatment plan (including route of administration) should be initiated promptly in H.L.?

Intensive, continuous, and immediate treatment can significantly reduce the mortality of thyroid storm. Mortality rates in thyroid storm are high, ranging between 20% and 30%.[192] Treatment of thyroid storm should be directed against four major areas discussed in the following sections.[192]

Decrease in Synthesis and Release of Hormones

High dosages of thioamides, preferably PTU 800 to 1,200 mg/day or methimazole 60 to 100 mg/day, should be given orally in four divided doses. If H.L. cannot take oral doses, a rectal formulation of PTU (better bioavailability with enema than suppository) or methimazole, which is as effective as the oral route, can be administered.[177–179] No commercial parenteral preparation is available for either drug, limiting their use by the IV route. PTU is the thioamide of choice because it acts more rapidly than methimazole by blocking the peripheral conversion of T_4 to T_3, a dominant source of the hormone.

Iodides, which rapidly block further release of intraglandular stores of T_4, should be given at least 1 hour after thioamide administration. Given in this way, the substrate for hormone synthesis is not increased, and the therapeutic effect of thioamide is not blocked. The addition of iodides (e.g., Lugol's solution 15 to 30 drops/day orally in divided doses) to the thioamides often ameliorates symptoms within 1 day.

Cholestyramine 4 g orally (PO) QID may assist in lowering hormone levels rapidly but should be administered apart from other agents to prevent inhibiting their absorption.[244] Other effective modalities include plasmapheresis, charcoal hemoperfusion, and plasma exchange.

Reversal of the Peripheral Effects of Hormones and Catecholamines

β-Adrenergic blocking drugs are the preferred agents to decrease the tachycardia, agitation, tremulousness, and other symptoms

---

of excessive adrenergic stimulation seen in thyroid storm. Propranolol is the β-blocker of choice because its clinical efficacy in storm is well documented, and it inhibits the peripheral conversion of T_4 to T_3.[192,200] If rapid effects are necessary, propranolol 1 mg by slow IV push can be given every 5 minutes to lower the heart rate to approximately 90 beats/minute. A 5- to 10-mg/hour IV infusion can maintain the desired heart rate. IV esmolol 50 to 100 mcg/kg/minute can also be given. If perfusion is maintained, oral β-blockers (e.g., propranolol, 40 mg every 6 hours; atenolol, 50–100 mg BID; metoprolol, 50–100 mg daily; nadolol, 40–80 mg daily), titrated to response, can also be given.

Supportive Treatment of Vital Functions

This may include sedation, oxygen, IV glucose, vitamins, treatment of infections with antibiotics, digitalization to maintain the cardiac status, rehydration, and treatment of hyperpyrexia with cooling blankets, sponge baths, and the judicious use of antipyretics. Because hypoadrenalism is often suspected, hydrocortisone 100 to 200 mg should empirically be given IV every 6 hours. Because pharmacologic doses of steroids acutely depress serum T_3 levels, a beneficial effect in storm, their routine use is recommended.

Elimination of Precipitating Causes of Storm

Precipitating causes of thyroid storm include infection (most common), trauma, inadequate preparation before thyroidectomy, surgical operations, stress, diabetic ketoacidosis, pregnancy, emboli, discontinuation or withdrawal of antithyroid medications, drug therapy, and RAI therapy.[192]

DRUG-INDUCED THYROID DISEASE

Lithium

CASE 52-23

QUESTION 1: D.A., a 56-year-old man, complains of sluggishness, cold intolerance, fatigue, and a “rundown” feeling, which doctors attribute to the depressive phase of his bipolar affective illness. He previously had been well controlled with sertraline 100 mg/day, but lithium carbonate 900 mg/day was added 4 months ago because of unreasonable mirthfulness and uncontrollable gift-buying tendencies. Physical examination reveals a puffy face and a large goiter. What is a reasonable assessment of these subjective and objective data?

Thyroid function tests (i.e., TSH, FT_4) and a thyroid ultrasound should be obtained to evaluate the possibility of lithium- and possibly sertraline-induced hypothyroidism and goiter.[4,5,13,245] If the TSH is elevated, T_4 should be initiated and lithium continued if necessary. Although the incidence of goiter and hypothyroidism in the manic-depressive population is unknown, the 10% incidence of baseline-elevated TSH appears higher than in the general population.

The exact mechanism of lithium’s antithyroid effect on the gland is unclear, although it is highly concentrated by the gland. Similar to the iodides, chronic lithium therapy inhibits the release of thyroid hormone from the gland. The fall in serum T_4 and T_3 hormone levels leads to a compensatory and transient increase in serum TSH levels until a new steady state is achieved.[4,5,13]

Elevated TSH levels are reported in approximately 19% of patients on chronic lithium therapy.[13] Typically, the serum thyroid hormone levels decrease and the TSH levels increase during the first few months of treatment, returning to pretreatment levels after 1 year. In one study, TSH levels increased within 10 days after starting therapy. Normalization of the TSH level is less likely to occur in patients with preexisting positive thyroid antibodies before lithium therapy. Induction of thyroid antibodies and increases in baseline antibody titers also occur after chronic lithium therapy. Because abnormal thyroid function tests can be transient, a longer period of observation is justified before starting thyroid therapy in patients with subclinical hypothyroidism.

Overt hypothyroidism appears in a small percentage of the population after 5 months to 2 years of therapy; one 15-year study found an incidence of 1.5% but an 8.4 relative risk in females with antibody positivity compared to negative subjects.[4,5,13] Lithium-induced goiter with or without hypothyroidism is common after weeks to months of therapy. Although incidences of less than 6% have been reported, higher rates of 40% to 60% are observed if the goiter is diagnosed using more specific imaging techniques (e.g. ultrasound). [4,5,13] A direct goitrogenic effect of lithium on inducing cell proliferation might explain the occurrence of euthyroid goiter. The goiters respond to discontinuation of lithium or to suppression with thyroid hormone despite continuation of lithium therapy. Surgical removal of the goiter is required if there are local obstructive symptoms. In D.A.’s case, sertraline could be exerting an additive or synergistic antithyroid effect with lithium because antithyroid effects have also been associated with this drug.[245]

Most patients with lithium-induced thyroid abnormalities are women older than 50 years, have a prior history of compromised thyroid function (e.g., Hashimoto's thyroiditis), positive thyroid antibodies before lithium therapy, or a strong family history of thyroid disease.[4,5,13] Therefore, baseline thyroid function tests (i.e., FT_4, TSH), antibodies, and thyroid ultrasound should be obtained before starting lithium therapy, and levels should be checked annually thereafter or more frequently if clinically indicated. Patients should also be questioned about a positive history or family history for thyroid disease and the concurrent use of other, potentially goitrogenic medications (e.g., tricyclic antidepressants, iodides, iodinated expectorants/herbals).

Iodides and Amiodarone

CASE 52-24

QUESTION 1: C.Y., a 54-year-old man with chronic atrial fibrillation presents with a 6-month history of weakness, fatigue, tremor, heat intolerance, and increased palpitations, previously controlled for the last 2 years on amiodarone 200 mg/day. Physical examination reveals a 50-g multinodular gland, which C.Y. says has "been there forever." He denies any family history of thyroid disease or ingestion of any thyroid medication. His current complaints began after a magnetic resonance imaging (MRI) procedure with iodinated radiocontrast media. What might be responsible for C.Y.'s hyperthyroid symptoms?

The iodine load from the MRI or the amiodarone could be responsible for C.Y.'s hyperthyroid symptoms.[3,12,17,28,57,173] Iodide-induced hyperthyroidism, or Jod-Basedow phenomenon, was first described in the 1800s when patients residing in iodide-deficient areas became toxic when given adequate iodide supplementation. Both T_3 toxicosis and classic T_4 toxicosis have been reported following iodide ingestion or injection of roentgenographic contrast media.

Although it is presumed that both iodide deficiency and a multinodular goiter, as in C.Y., are required to invoke the Jod-Basedow phenomenon, iodide-induced disease has been reported in patients residing in iodide-sufficient areas, as well as in euthyroid patients with normal glands and no apparent risk

---

factors (e.g., family history).[28,173]

Amiodarone can cause hypo- or hyperthyroidism in susceptible patients because of its high iodine content.[3,12,16,17,28,57,173] Twelve milligrams (37%) of free iodine is released per 400-mg dose of amiodarone. Patients with multinodular goiters, who lose the ability to turn off iodide organification from increased iodide loads (Wolff–Chaikoff effect), are most likely to develop iodide-induced thyrotoxicosis.

Conversely, patients with positive antibodies or with underlying Hashimoto's thyroiditis, who cannot escape from the Wolff–Chaikoff block, are most likely to develop hypothyroidism.

Amiodarone-induced hypothyroidism may occur at any time during therapy and does not appear to be related to the cumulative dose. A low-normal or low FT_4 and a persistently elevated TSH (see Case 52-4) are consistent with amiodarone-induced hypothyroidism, which occurs in 6% to 10% of long-term users. The hypothyroidism responds readily to T_4 therapy, even if the amiodarone is continued.[3,17,57] Amiodarone-induced hypothyroidism typically resolves after stopping the drug, but resolution may be delayed because of its long half-life.

In contrast, amiodarone-induced thyrotoxicosis, which occurs in 1% to 5% of long-term users, occurs early and suddenly during therapy, so that routine monitoring of thyroid function tests is not useful. Elevated hormone levels, an undetectable TSH level, and clinical symptoms consistent with hyperthyroidism are the best indicators of amiodarone-induced thyrotoxicosis. Worsening of tachyarrhythmias may be the first clinical clue to amiodarone-induced thyrotoxicosis.

Amiodarone-induced hyperthyroidism can be classified as either type I or type II.[3,12,55,57] Type I occurs in patients with underlying risk factors for thyroid disease (e.g., multinodular goiter) and is related to the iodine load. The formation of large amounts of preformed hormone from the massive iodine load produces a protracted course of hyperthyroidism, which is challenging to manage. Type II amiodarone-induced hyperthyroidism is because of a destructive thyroiditis, with excessive release of thyroid hormone into the systemic circulation. This occurs most often in patients with normal thyroid glands. Unique laboratory findings include a low RAIU and elevated interleukin-6 levels.

The management of amiodarone-induced thyrotoxicosis is complicated because it is not always possible to identify the type of hyperthyroidism and a mixture of the two types can occur. Stopping amiodarone alone does not immediately improve the hyperthyroidism because of the drug's long half-life (22–55 days) and its sequestration in fat. RAI ablation is never effective because the high iodine load from amiodarone will suppress RAI uptake. The combination of methimazole and potassium perchlorate is the treatment of choice for type I hyperthyroidism.[3,12,17,28,57,173] The addition of corticosteroids to block T_4 to T_3 conversion is less effective because of the already potent inhibitory effects of amiodarone on T_4 to T_3 conversion. However, in patients with type II hyperthyroidism, agents that block T_4 to T_3 conversion (e.g., β-blockers, corticosteroids, and iodinated contrast media if available), rather than the aforementioned agents, are the most appropriate choices.[3,17,28,57,246] A total thyroidectomy can rapidly control the thyrotoxicosis, permitting continued therapy with amiodarone if necessary. Despite underlying cardiac disease in these patients, uneventful surgery and a low complication rate have been observed if patients are treated before surgery with a short course of an oral cholecystographic agent.[246]

Changing amiodarone to dronedarone which is devoid of iodine and lacks the undesirable thyroid effects should be strongly considered in C.Y.

Large doses of iodides should be avoided in patients with nontoxic multinodular goiters, who are predisposed to thyrotoxicosis (see Case 52-4 and Case 52-15, Question 2).

Thyrotropin-α and Thyroid Suppression Therapy for Thyroid Cancer

CASE 52-25

QUESTION 1: J.R., a 28-year-old man, had a total thyroidectomy last year for papillary cancer followed by RAI therapy. He is clinically euthyroid on 200 mcg L-thyroxine daily with a TSH level of <0.2 microunits/mL (normal, 0.45–4.1). He is hesitant to discontinue his L-thyroxine, so that an RAIU scan and thyroglobulin testing can be done to evaluate for tumor recurrence. His doctor is concerned about his suppressed TSH level and is also worried about taking J.R. off his L-thyroxine because the patient says he "feels incapacitated" while carrying out these tests. What can you tell his physician about the TSH level and the need to stop L-thyroxine during these tests?

In patients with thyroid cancers, total thyroidectomy, followed by RAI and L-thyroxine therapy to suppress the TSH to subnormal levels, were associated with improved overall survival.[247] The actual degree of thyroid suppression required is complex and depends upon the severity and extent of the thyroid cancer and the likelihood of a disease-free prognosis. The benefits of prolonged thyrotropin suppression to prevent cancer recurrence need to be balanced against the risks and adverse effects (e.g. osteoporosis, cardiac toxicity) of lifelong T_4 suppression. Lifelong TSH suppression to a level of <0.1 microunits/mL is preferred for patients with high-to-intermediate risk of recurrent cancer or metastastes. [29] A low normal TSH of 0.3 to 2 microunits/mL can be considered for disease-free patients. It is important to annually assess recurrence of the malignancy by determining whether any residual cancerous or normal thyroid tissue remains. This is done either by withdrawing suppressive T_4 therapy and allowing endogenous TSH concentrations to rise or by administering recombinant human TSH (thyrotropin-α). If any functioning follicular cells remain, the rise in TSH will cause a rise in thyroglobulin and/or positive RAIU, indicating a need for further RAI therapy. Thyrotropin-α (Thryogen) may be preferred because it allows screening without the troublesome hypothyroid symptoms caused by withdrawal of T_4.[248] Thyrotropin-α failed to detect localized tumor recurrence in 7% of patients compared to 100% detection after hormone withdrawal but detected 100% of patients with metastatic disease.[29,248]

J.R. should be maintained on his current L-thyroxine suppression dosage because his TSH level is appropriately suppressed without hyperthyroidism.

Diabetes Mellitus

Jennifer D. Goldman, Dhiren K. Patel, and David Schnee

	CORE PRINCIPLES	CHAPTER CASES
①	A glycosylated hemoglobin (A1C) level can be used to diagnose diabetes, in addition to a fasting plasma glucose (FPG) or oral glucose tolerance test (OGTT). Each test must be confirmed on a subsequent day.	**Case 53-2 (Question 1), Case 53-11 (Question 1)**
②	The primary metabolic goals for diabetes are an A1C less than 7%, a systolic blood pressure less than 140 mm Hg, and statin therapy for most patients over the age of 40. Management of cholesterol should include a statin drug, and management of hypertension should include an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker.	**Case 53-2 (Question 2), Case 53-11 (Question 2)**
③	Glycemic treatment goals should be individualized. For patients with a short duration of diabetes, long life expectancy, and no significant vascular disease, more stringent goals can be considered, if it can be achieved without increasing hypoglycemia. For patients with existing vascular disease, other significant macrovascular or microvascular disease, a history of hypoglycemia, or limited life expectancy, or for those with long-standing diabetes who have difficulty lowering their A1C, a less stringent A1C goal should be considered.	**Case 53-2 (Question 2), Case 53-4 (Question 2), Case 53-11 (Question 2), Case 53-18 (Question 3)**
④	Medical nutrition therapy (MNT) and physical activity are cornerstones to the treatment of diabetes.	**Case 53-2 (Questions 11, 12), Case 53-11 (Question 3), Case 53-18 (Question 4)**
⑤	Self-monitoring of blood glucose (SMBG) should be performed by all patients with Type 1 diabetes and most patients with Type 2 diabetes, particularly those on antidiabetic therapy that can cause hypoglycemia or those engaged in self-management. The key to SMBG is to educate patients on how to respond to their blood glucose (BG) levels.	**Case 53-2 (Questions 9–11), Case 53-4 (Question 5), Case 53-11 (Question 6)**
⑥	Basal-bolus insulin regimens should be used for patients with Type 1 diabetes. These can be administered either by multiple daily injections or by an insulin pump. Basal-bolus insulin regimens are also effective for patients with Type 2 diabetes who no longer are able to achieve A1C goals with noninsulin therapies.	**Case 53-2 (Questions 3–6), Case 53-4 (Question 3), Case 53-13 (Question 6)**
⑦	Metformin is the first-line therapy for Type 2 diabetes unless a patient	**Case 53-11 (Questions 3–5)**

	has a contraindication to its use or is unable to tolerate this agent. It should be added at diagnosis along with lifestyle changes.	
⑧	After monotherapy, a second antidiabetic agent should be added to the regimen. Factors to consider include the patient's A1C goal, the amount of reduction in A1C required, the patient's kidney and liver function, medication side effects, and cost of therapy.	**Case 53-11 (Question 7),** **Case 53-12 (Question 1),** **Case 53-13 (Questions 2–4)**
⑨	In Type 2 diabetes, insulin therapy should be considered any time the patient's A1C is severely uncontrolled (e.g., A1C >10%) and also when the A1C is more than 8.5% to 9%, and a patient is already on combination oral therapy. It should be considered whether a patient is symptomatic.	**Case 53-11 (Question 7),** **Case 53-12 (Question 1),** **Case 53-13 (Question 5)**
⑩	Owing to concerns about the effects of hypoglycemia and new trials indicating a lack of benefit of very tight glucose control in acutely ill patients, the current-recommended goal BG in hospitalized patients is 140 to 180 mg/dL.	**Case 53-7 (Question 1)**
⑪	Although acute hyperglycemic crises can occur in patients with diabetes, most morbidity and mortality occurs over the course of years and can be classified as either microvascular (nephropathy, neuropathy, and retinopathy) or macrovascular (coronary heart disease (CHD), stroke, and peripheral vascular disease).	**Case 53-19 (Questions 1–5),** **Case 53-20 (Questions 1–3)**
⑫	Patients with established vascular disease should remain on lifelong aspirin therapy, whereas patients without established vascular disease need to be carefully considered to determine the appropriateness of antiplatelet therapy.	**Case 53-19 (Question 6)**
⑬	The incidence and severity of microvascular complications has a strong correlation with long-term glycemic control as measured by A1C. Macrovascular complications are influenced by glycemic control, but are more dependent on multiple etiologic factors including dyslipidemia, hypertension, and smoking.	**Case 53-11 (Question 2)**

An estimated 29.1 million people, or 9.3% of the US population, currently have diabetes.[1] Of these, 8.1 million or about one-third are undiagnosed. In 2012 alone, more than 1.7 million new cases in adults were diagnosed. Globally, the prevalence of diabetes for all ages is estimated to be 2.8% in 2000 and projected to increase to 4.4% by 2030.[2] The incidence of Type 2 diabetes is now epidemic, with alarming increases in prevalence in both adults and children. Estimates by the Centers for Disease Control and Prevention indicate that new cases of diabetes annually will increase from 8/1,000 people to about 15/1,000 in 2050, with as many as 1 in 3 Americans having diabetes in 2050.[3] The dramatic increase in Type 2 diabetes in the population is related to obesity and decreased physical activity levels, and also the fact that people with diabetes are living longer. Additional individual factors include a genetic predisposition for increased insulin resistance and progressive β-cell failure. Clinical studies have affirmed that Type 2 diabetes can be delayed or prevented in high-risk populations and that good glycemic control and other interventions can slow its devastating complications.[4]

DEFINITION, CLASSIFICATION, AND EPIDEMIOLOGY

Diabetes is a chronic condition caused by an absolute lack of insulin or relative lack of insulin as a result of impaired insulin secretion and action. Its hallmark clinical characteristics are symptomatic glucose intolerance resulting in hyperglycemia and alterations in lipid and protein metabolism. In the long term, these metabolic abnormalities contribute to the development of complications such as cardiovascular disease (CVD), retinopathy, nephropathy, and neuropathy and a higher risk of cancer.[5,6]

Genetically, etiologically, and clinically, diabetes is a heterogeneous group of disorders. Nevertheless, most cases of diabetes mellitus can be assigned to Type 1 or Type 2 diabetes (Table 53-1). The term gestational diabetes mellitus (GDM) is used to describe glucose intolerance that has its onset during pregnancy. Glucose intolerance that cannot be ascribed to causes consistent with these three classifications includes specific genetic defects in β-cell function or insulin action (usually genetically defective insulin receptors); diseases of the exocrine pancreas; endocrinopathies; drug- or chemical-induced; infections; and other genetic syndromes. Early glucose intolerance or "prediabetes" is identified as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT), and they are considered risk factors for the future development of diabetes and are associated with obesity, hypertriglyceridemia, and/or low high-density lipoprotein (HDL) cholesterol and hypertension.[7]

Approximately 5% to 10% of the diagnosed diabetic population has Type 1 diabetes, which usually results from autoimmune destruction of the pancreatic β-cells. At clinical presentation, these patients have little or no pancreatic reserve, have a tendency to develop ketoacidosis, and require exogenous insulin to sustain life. The incidence of autoimmune-mediated Type 1 diabetes peaks during childhood and adolescence, but it can occur at any age. A minority of patients diagnosed with Type 1 diabetes, mostly of African or Asian ancestry, can have no evidence of autoimmunity; the etiology is, therefore, unknown. In these individuals, the rate of pancreatic destruction seems to occur more slowly, leading to a later onset and less acute presentation.[7]

Most people with diabetes have Type 2 diabetes, a heterogeneous disorder that is characterized by obesity, β-cell dysfunction, resistance to insulin action, and increased hepatic glucose production. Both the incidence and prevalence of diabetes increase dramatically with age, obesity, and lack of physical activity.[7] In the United States, the percentage of patients with diagnosed or undiagnosed diabetes in those 20 to 44 years of age is 4.1%. This increases to 25.9% in those 65 and older.[1] The prevalence of Type 2 diabetes also differs among ethnic populations. Relative to non-Hispanic whites (7.6%), the prevalence of diagnosed diabetes is higher in Asian-Americans (9%), Hispanics (12.8%), African-Americans (13.2%), and American Indians and Alaskan Natives (15.9%).[1] Diabetes is a serious condition that places people at risk for greater morbidity and mortality relative to the nondiabetic population. Diabetes is the seventh leading cause of death in the United States, although deaths attributed to diabetes and its complications are likely to be underreported. Compared with the general population, the mortality rate for people with diabetes is about twice that for people without diabetes.[1]

Medical management of people with diabetes is costly. In 2012, the total cost of diabetes in the United States was estimated to be $245 billion, with 1 of 5 healthcare dollars being spent on people with diabetes.[8] The average healthcare expenditures for people with diabetes were approximately 2.3 times higher than those for individuals without diabetes. The majority (56%) of all healthcare expenditures attributed to diabetes are used by people aged 65 years and older. Hospital inpatient costs, nursing facility resources, home care, physician visits, and medications (not just diabetes agents) made up the majority of these expenditures. Because many expenditures are related to treatment of long-term complications, considerable effort has been directed toward early diagnosis and metabolic control of patients with diabetes.[8]

Table 53-1

Type 1 and Type 2 Diabetes

Characteristics	Type 1	Type 2
Other names	Previously, type I; insulin-dependent diabetes mellitus (IDDM); juvenile-onset diabetes mellitus	Previously, type II; non-insulin-dependent diabetes mellitus (NIDDM); adult-onset diabetes mellitus
Percentage of diabetic population	5%–10%	90%
Age at onset	Usually <30 years; peaks at 12–14 years; rare before 6 months; some adults develop type 1 during the fifth decade	Usually >40 years, but increasing prevalence among obese children

Pancreatic function	Usually none, although some residual C-peptide can sometimes be detected at diagnosis, especially in adults	Insulin present in low, “normal,” or high amounts
Pathogenesis	Associated with certain HLA types; presence of islet cell antibodies suggests autoimmune process	Defect in insulin secretion; tissue resistance to insulin; ↑ hepatic glucose output
Family history	Generally not strong	Strong
Obesity	Uncommon unless “overinsulinized” with exogenous insulin	Common (60%–90%)
History of ketoacidosis	Often present	Rare, except in circumstances of unusual stress (e.g., infection)
Clinical presentation	Moderate-to-severe symptoms that generally progress relatively rapidly (days to weeks): polyuria, polydipsia, fatigue, weight loss, ketoacidosis	Mild polyuria, fatigue; often diagnosed on routine physical or dental examination
Treatment	MNT	MNT
	Physical activity	Physical activity

DPP-4, dipeptidyl peptidase-4; HLA, human leukocyte antigen; MNT, medical nutrition therapy.

CARBOHYDRATE METABOLISM

An understanding of the signs and symptoms associated with diabetes is based on a knowledge of glucose metabolism and the metabolic effects of insulin in nondiabetic and diabetic subjects during the fed (postprandial) and fasting (postabsorptive) states.[9] Homeostatic mechanisms maintain plasma glucose concentrations between 55 and 140 mg/dL. A minimum concentration of 40 to 60 mg/dL is required to provide adequate fuel for the central nervous system, which uses glucose as its primary energy source and is independent of insulin for glucose utilization. When BG concentrations exceed the reabsorptive capacity of the proximal tubule in the kidneys (~180 mg/dL), glucose spills into the urine (glucosuria), resulting in a loss of calories and water. Muscle and fat, which use glucose as a major source of energy, require insulin for glucose uptake. If glucose is unavailable, these tissues are able to use other substrates such as amino acids and fatty acids for fuel.[9]

Postprandial Glucose and Lipid Metabolism in the

Nondiabetic Individual

After food is ingested, BG concentrations rise and stimulate insulin release. Insulin is the key to efficient glucose utilization. It promotes the uptake of glucose, fatty acids, and amino acids, and their conversion to storage forms in most tissues. Insulin also inhibits hepatic glucose production by suppressing glucagon and its effects. In muscle, insulin promotes the uptake of glucose and its storage as glycogen. It also stimulates the uptake of amino acids and their conversion to protein. In adipose tissue, glucose is converted to free fatty acids and stored as triglycerides. Insulin also prevents a breakdown of these triglycerides to free fatty acids, a form that may be transported to other tissues for utilization. The liver does not require insulin for glucose transport, but insulin facilitates the conversion of glucose to glycogen and free fatty acids.[9,10]

Free fatty acids are esterified to triglycerides, which are transported by very-low-density lipoproteins (VLDLs) to adipose and muscle tissue. Normal insulin signaling suppresses VLDL secretion by reducing the production of fatty acids in the liver.[10] Once secreted by the liver, VLDL is acted on primarily by hepatic lipase in the liver and by lipoprotein lipase on endothelial cells.[10] Acting through apolipoprotein (apo) CII on the surface of the VLDL particle, these lipases remove free fatty acids from the lipoprotein and convert VLDL to intermediate-density lipoprotein (IDL) and then IDL to low-density lipoprotein (LDL). Insulin plays a role in stimulating apoCII expression, which partly explains the hypertriglyceridemia that occurs in Type 2 diabetes.[10]

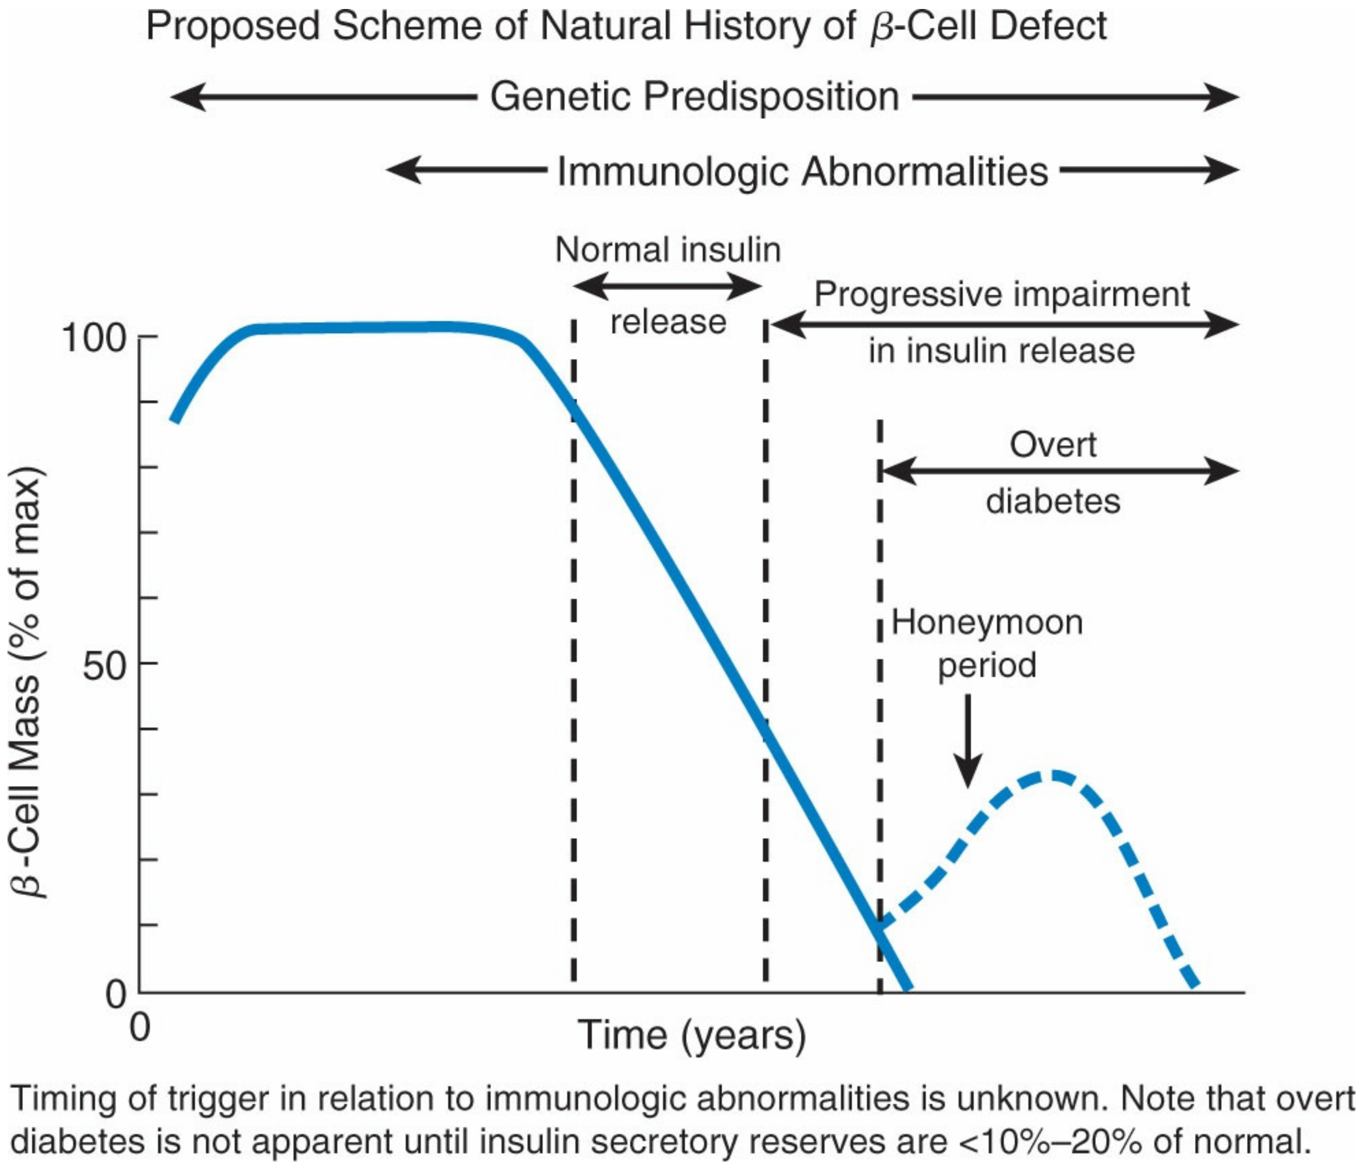
Fasting Glucose Metabolism in the Nondiabetic Individual

As BG concentrations drop toward normal during the fasting state, insulin release is inhibited. Simultaneously, a number of counter-regulatory hormones that oppose the effect of insulin and promote an increase in blood sugar are released (e.g., glucagon, epinephrine, growth hormone, cortisol). As a result, several processes maintain a minimum BG concentration for the central nervous system. Glycogen in the liver is broken down into glucose (glycogenolysis). Amino acids are transported from muscle to liver, where they are converted to glucose through gluconeogenesis. Uptake of glucose by insulin-dependent tissues is diminished to conserve glucose for the brain. Finally, triglycerides are broken down into free fatty acids, which are used as alternative fuel sources.[9,10]

TYPE 1 DIABETES

Pathogenesis

The loss of insulin secretion in Type 1 diabetes mellitus results from autoimmune destruction of the insulin-producing β-cells in the pancreas, which is thought to be triggered by environmental factors, such as viruses or toxins, in genetically susceptible individuals.[7,11] This form of diabetes is associated closely with histocompatibility antigens (human leukocyte antigen [HLA]-DR3 or HLA-DR4) and the presence of circulating antibodies, including insulin autoantibodies, glutamic acid decarboxylase autoantibodies (GAD65), islet cell autoantibodies (ICA), and autoantibodies to tyrosine phosphatases (e.g., islet cell antibody 512). The capacity of normal pancreatic β-cells to secrete insulin far exceeds the normal amounts needed to control carbohydrate, fat, and protein metabolism. As a result, the clinical onset of Type 1 diabetes is preceded by an extensive asymptomatic period during which β-cells are destroyed (Fig. 53-1). β-cell destruction may occur rapidly, but is more likely to take place over a period of weeks, months, or even years. The earliest detectable abnormality in insulin secretion is a progressive reduction of immediate or first-phase plasma insulin response. However, this initial impairment has few detrimental effects on overall glucose homeostasis, and plasma glucose concentrations remain normal. Most affected individuals have circulating antibodies to islet cells or to their own insulin at this stage of the disease. These represent markers of an ongoing autoimmune process that culminates in Type 1 diabetes. Fasting hyperglycemia occurs when the β-cell mass is reduced by 80% to 90%. One or more of the above autoantibodies is usually present in 85% to 90% of individuals at this point. Initially, only postprandial hyperglycemia occurs, but as insulin secretion becomes further compromised, progressive fasting hyperglycemia is seen. Within 8 to 10 years of clinical presentation, β-cell loss is complete and insulin deficiency is absolute.[7,11]



Proposed Scheme of Natural History of β-Cell Defect

Timing of trigger in relation to immunologic abnormalities is unknown. Note that overt diabetes is not apparent until insulin secretory reserves are <10%–20% of normal.

Figure 53-1 Pathogenesis of type 1 diabetes. In an individual with a genetic predisposition, an event (such as a virus or toxin) triggers autoimmune destruction of the pancreatic β-cells, probably during a period of several years. When the number of β-cells diminishes to approximately 250,000, the pancreas is unable to secrete sufficient insulin and intolerance to glucose ensues. At this point, a stressful event, such as a viral infection, can produce acute symptoms of hyperglycemia and ketoacidosis. Once the acute event has passed, the pancreas temporarily recovers, leading to a remission (honeymoon period). Continued destruction of the β-cell ultimately leads to an insulin-dependent state.

Clinical Presentation

Although the onset of Type 1 diabetes seems to be abrupt, evidence now exists for an extended preclinical period that can precede obvious symptoms by several years. Because insulin secretion becomes compromised, progressive fasting hyperglycemia occurs. Glucosuria, which occurs when BG levels exceed the renal threshold, results in an osmotic diuresis, producing the classic symptoms of polyuria with compensatory polydipsia. If symptoms are untreated, weight loss occurs because glucose calories are lost in the urine and body fat and protein stores are broken down owing to increased rates of lipolysis and proteolysis. Muscle begins to metabolize its own glycogen stores and fatty acids for fuel, and the liver begins to metabolize free fatty acids that are released in response to epinephrine and low insulin concentrations. An absolute lack of insulin may cause excessive mobilization of free fatty acids to the liver, where they are metabolized to ketones. This can result in ketonemia, ketonuria, and, ultimately, ketoacidosis. Patients present with complaints of fatigue, significant weight loss, polyuria, and polydipsia. A significant elevation in A1C confirms weeks or months of preceding hyperglycemia.

Because glucose provides an excellent medium for microorganisms, patients may present also with recurrent respiratory, vaginal, and other infections. Patients also may experience blurred vision secondary to osmotically induced changes in the lens of the eye. Treatment with insulin is essential to prevent severe dehydration, ketoacidosis, and death.

Honeymoon Period

Within days or weeks after the initial diagnosis and implementing treatment, many patients with Type 1 diabetes experience an apparent remission, which is reflected by decreased BG concentrations and markedly decreased insulin requirements. This is called the honeymoon period because it may last for only a few weeks to months. Once hyperglycemia, metabolic acidosis, and ketosis resolve, endogenous insulin secretion recovers temporarily (Fig. 53-1). Although the honeymoon period may last for up to a year, increasing exogenous insulin requirements are inevitable and should be anticipated. During this time, patients should be maintained on insulin even if the dose is very low, because interrupted treatment is associated with a greater incidence of resistance and allergy to insulin.

TYPE 2 DIABETES

Pathogenesis

Type 2 diabetes is characterized by impaired insulin secretion and resistance to insulin action. In the presence of insulin resistance, glucose utilization by tissues is impaired, hepatic glucose and free fatty acid production is increased, and excess glucose accumulates in the circulation. This hyperglycemia stimulates the pancreas to produce more insulin in an attempt to overcome insulin resistance. The simultaneous elevation of both glucose and insulin levels is strongly suggestive of insulin resistance. Genetic predisposition may play a role in the development of Type 2 diabetes. People with Type 2 diabetes have a stronger family history of diabetes than those with Type 1. There is no association with HLA types, however, and circulating ICAs are absent.[7,12] People with Type 2 diabetes also exhibit varying degrees of tissue resistance to insulin, impaired insulin secretion, and increased basal hepatic glucose production. Finally, environmental factors such as obesity and a sedentary lifestyle also contribute to the development of insulin resistance.

Despite being the most common form of diabetes, the exact pathogenesis of Type 2 is less well understood. Basal insulin levels are typically normal or elevated at diagnosis. First- or early-phase insulin release in response to glucose often is reduced, and pulsatile insulin secretion is absent, resulting in postprandial hyperglycemia. The effects of other insulinotropic substances such as incretin hormones, which contribute to meal-stimulated insulin release, are also altered.[13] With time, β-cells lose their ability to respond to elevated glucose concentrations, leading to increasing loss of glucose control. In patients with severe hyperglycemia, the amount of insulin secreted in response to glucose is diminished and insulin resistance is worsened (glucose toxicity).

Most individuals with Type 2 exhibit decreased tissue responsiveness to insulin.[12] Excess weight or hyperglycemia may contribute to hyperinsulinemia, which in time may lead to a decrease in or downregulation of the number of insulin receptors on the surface of target tissues and organs. Evidence suggests that decreased peripheral glucose uptake and utilization in muscle is the primary site of insulin resistance and results in prolonged postprandial hyperglycemia. Resistance may be secondary to decreased numbers of insulin receptors on the cell surface, decreased affinity of receptors for insulin, or defects in insulin signaling and action that follows receptor binding. Defects in insulin signaling and action are referred to as postreceptor or postbinding defects and are likely to be the primary sites of insulin resistance.

Patients with Type 2 diabetes also exhibit increased hepatic glucose production (glycogenolysis and gluconeogenesis) reflected by an elevated fasting plasma or BG concentration.[12] As noted, hepatic glucose production is the primary source of glucose in the fasting state. In patients with Type 2 diabetes, altered hepatic glucose production may also contribute to or cause postprandial hyperglycemia. Glucagon, produced by the α-cells in the pancreatic islets and secreted in response to low BG, stimulates hepatic glucose production.[14] Its production is inhibited by insulin. Glucagon response to carbohydrate ingestion is altered in patients with Type 2 diabetes who have a defective or absent early insulin response secondary to β-cell dysfunction or failure. For patients with Type 2 diabetes, untreated fasting and postprandial hyperglycemia caused by decreased glucose uptake and increased hepatic glucose production, hyperinsulinemia, and insulin resistance lead to a vicious cycle that inflicts ongoing damage to tissues and organs.

Patients with Type 2 diabetes are often subclassified based on weight. Obese individuals account for more than 80% of patients with Type 2 diabetes.[12] Patients with Type 2 diabetes who are not obese often have increased body fat distributed in the abdominal area. Nonobese individuals account for about 10% of the Type 2 population. Typically, they develop a mild form of diabetes during childhood, adolescence, or as young adults (usually before age 25), and their insulin levels are low in response to a glucose challenge. Included in this group are patients who have maturity-onset diabetes of the young (MODY).[7,12] MODY is associated with a strong family history that suggests an autosomal-dominant transmission. The underlying defect is heterogeneous, and multiple abnormalities at loci on different chromosomes have been discovered. More common defects include those for hepatic transcription factors and glucokinase (the "glucose sensor" in β-cells). Patients with MODY may present with moderate-to-severe symptoms with or without ketosis. Unlike Type 1 diabetes, however, the disease generally is mild and controlled with diet, oral agents, or low doses of insulin. With the increasing prevalence of obesity and Type 2 diabetes in children and adolescents, it is important to distinguish between a youth with Type 2 diabetes and one who really has autoimmune Type 1 diabetes and is also obese.[15]

Type 2 diabetes is associated with a variety of disorders, including dyslipidemia, hypertension, and premature atherosclerosis (Fig. 53-2). Currently termed the metabolic syndrome, this triad of clinical findings (hypertension, elevated fasting glucose, and dyslipidemia) is proposed to derive from insulin resistance itself and the resulting compensatory hyperinsulinemia.[16] The labeling of this triad as a separate "syndrome" remains the subject of considerable debate, partly because it appears to have little diagnostic utility beyond its component parts.[17] Metabolic syndrome is common in the United States, with an estimated prevalence of more than 34% in adults aged 20 and older, peaking among those 60 to 69 years of age.[18] Because it is highly correlated with cardiovascular events, the National Cholesterol Education Program has suggested criteria for the diagnosis of metabolic syndrome.[19] Not all individuals with the metabolic syndrome progress to IGT or diabetes, but those who do may be genetically predisposed to β-cell dysfunction. Figure 53-3 depicts the typical dyslipidemia pattern seen in diabetes and how insulin resistance affects normal lipoprotein metabolism.

IFG, IGT Type 2 Diabetes

Figure 53-2 Metabolic syndrome. Genetic and environmental factors (visceral obesity, sedentary lifestyle, aging) predispose some individuals to insulin resistance. To overcome the resistance, the pancreas secretes more insulin, leading to hyperinsulinemia. People with insulin resistance and hyperinsulinemia commonly develop a cluster of medical problems and biochemical abnormalities: cardiovascular disease, hypertension, dyslipidemia, hyperuricemia, and type 2 diabetes mellitus. Only those individuals who are further genetically predisposed to β-cell failure go on to develop IGT, IFG, and type 2 diabetes. Many people with type 2 diabetes already have evidence of cardiovascular disease at the time of diabetes diagnosis. The cause-and-effect relationship between insulin resistance or hyperinsulinemia and these clinical conditions has not been clarified. See text for expanded discussion. Figure 53-3 Changes in lipoprotein metabolism are a direct consequence of insulin resistance and are present before the onset of overt diabetes.

Clinical Presentation

Type 2 diabetes is typically diagnosed incidentally during a routine physical examination or when the patient seeks attention for another complaint. Because symptoms are mild in their onset, patients will rarely complain of fatigue, polyuria, and polydipsia but may admit to them during clinical examination. Because these patients have sufficient insulin concentrations to prevent lipolysis, there is usually no history of ketosis except in situations of unusual stress (e.g., infections, trauma). Weight loss is therefore uncommon because relatively high endogenous insulin levels promote lipogenesis. Macrovascular disease is also often evident at diagnosis. Microvascular complications at diagnosis suggest the presence of undiagnosed or subclinical diabetes for 7 to 10 years. Because Type 2 diabetes patients retain some pancreatic reserve at the time of diagnosis, they generally can be treated with MNT, physical activity, and noninsulin antidiabetic medications for several years. Nevertheless, many eventually require insulin for control of their symptoms.

Screening

The ADA advises that adults without risk factors should be screened starting at age 45.[7] Repeat testing should take place every 3 years if results are normal or yearly if they have prediabetes. Adults may be tested at a younger age and more frequently if they are overweight (body mass index [BMI] ≥25 or 35 kg/m^2 in Asian-Americans) and have one or more of the risk factors listed in Table 53-2. A FPG or A1C is preferred over the OGTT to test for diabetes, because they are much less cumbersome. Asymptomatic children who are age 10 or who experience the onset of puberty before age 10 should be screened every 2 years for Type 2 diabetes if they are overweight (BMI >85th percentile for age and sex; weight for height >85th percentile; or weight >120% of ideal for height) and have two or more of the risk factors listed in Table 53-2.[7]

GESTATIONAL DIABETES MELLITUS

GDM affects about 7% of all pregnancies and is defined as "any carbohydrate intolerance with onset or first recognition during pregnancy."[7,20] The onset of diabetes during pregnancy and its duration affect the prognosis for a good obstetric and perinatal outcome (see Chapter 49, Obstetric Drug Therapy).

Diagnostic Criteria

The categories for normal, increased risk for diabetes, and diabetes for FPG, A1C, and the OGTT are listed in Table 53-3.[7] The Expert Committee of the ADA has established the diagnostic criteria for diabetes for nonpregnant individuals of any age. For these individuals, a diagnosis of diabetes can be made when one of the following is present[7]:

1. An A1C of 6.5% or more. The test must be performed in a laboratory (not with a point-of-care test). It should be performed using a method certified by the National Glycohemoglobin Standardization Program.
2. An FPG of 126 mg/dL or more. Fasting means no caloric intake for at least 8 hours.
3. Classic signs and symptoms of diabetes (polyuria, polydipsia, ketonuria, and unexplained weight loss) combined with a random plasma glucose of 200 mg/dL or more.
4. After a standard OGTT (75 g of glucose for an adult or 1.75 g/kg for a child), the venous plasma glucose concentration is 200 mg/dL or more at 2 hours.

The diagnosis must be confirmed by repeating the test, preferably the same test. If two different tests are performed (e.g., FPG and A1C), and both are above the diagnostic threshold, then diabetes is confirmed. If only one test's value is above the diagnostic cut point, the test that is above the diagnostic cut point should be repeated. The diagnosis is made based on the results of the confirmed test.[7]

At times, it may be difficult to classify patients as having Type 1 or Type 2 diabetes mellitus. Type 1 is more likely when a patient is younger than 30 years of age and lean, and has an elevated FPG and signs and symptoms of diabetes. The presence of moderate ketonuria with hyperglycemia in an otherwise unstressed patient also strongly supports a diagnosis of Type 1 diabetes. Absence of ketonuria, however, is not of diagnostic value. The presence of autoantibodies to insulin or islet cell components may also indicate the need for eventual insulin therapy.[11] Relatively, lean older adults believed to have Type 2 diabetes because they are initially responsive to oral agents or low doses of insulin may be subsequently diagnosed with Type 1 diabetes. In addition, clinicians are beginning to observe more cases of Type 2 diabetes in obese children and adolescents.[21]

Table 53-2

Risk Factors for Type 2 Diabetes Mellitus[7]

Adults	Children[a]
Overweight (≥25 kg/m^2) or (≥23 kg/m^2) in Asian-Americans	Overweight (BMI >85th percentile for age and sex; or weight >120% of ideal for height)
Family history of diabetes (first-degree relative)	Family history of diabetes (first- or second-degree relative)
Physical inactivity	
Ethnic predisposition[b]	Ethnic predisposition[b]
Previous IFG, IGT, or A1C ≥5.7%	
History of PCOS, GDM, or macrosomia	Maternal history of diabetes (including GDM)
Clinical conditions associated with insulin resistance (e.g., severe obesity and acanthosis nigricans)	Signs of insulin resistance (e.g., acanthosis nigricans)
Hypertension (≥140/90 mm Hg or on antihypertensive therapy)	Conditions associated with insulin resistance (e.g., hypertension, dyslipidemia, or PCOS)
Dyslipidemia	
HDL-C <35 mg/dL (0.90 mmol/L)	
Triglyceride >250 mg/dL (2.82 mmol/L)	
Cardiovascular disease	

[a] Children are younger than 18 years of age.

[b] Ethnic predisposition includes individuals of African-American, Latino, Native American, Asian, or Pacific Islander descent.

A1C, glycosylated hemoglobin; BMI, body mass index; GDM, gestational diabetes mellitus; HDL-C, high-density lipoprotein cholesterol; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; PCOS, polycystic ovarian syndrome.

Table 53-3

Normal and Diabetic Plasma Glucose Levels in mg/dL (mmol/L) and

Glycosylated Hemoglobin (A1C) and Normal and Diabetic Plasma Glucose Levels for the Oral Glucose Tolerance Test (OGTT)[7]

	FPG	A1C	OGTT
Normal	<100 (5.6)	≤5.6%	<140 (7.8)
Prediabetes (i.e., impaired fasting glucose (IFG), impaired glucose tolerance (IGT))	100–125 (5.6–6.9)	≥5.7–6.4%	140–199 (7.8–11.0)
Diabetes (nonpregnant adult)	≥126 (7.0)	≥6.5%	≥200 (11.1)

Equivalent venous whole-blood glucose concentrations are approximately 12%–15% lower. Arterial samples are higher than venous samples postprandially because glucose has not yet been removed from peripheral tissues. Capillary whole-blood samples contain a mixture of arterial and venous blood. Fasting levels are equivalent to whole-blood venous samples.

A1C, glycosylated hemoglobin; FPG, fasting plasma glucose; OGTT, oral glucose tolerance test.

Individuals with A1C, FPG, or OGTT values that are intermediate between normal and those considered diagnostic of diabetes are considered to have prediabetes. The terms IFG and IGT should not be used interchangeably because each results from somewhat different physiologic processes. It is important to interpret the categories listed in Table 53-3 as a continuum of increased risk for diabetes, rather than focus on the absolute cutoff points for prediabetes or diabetes.

Many factors can impair glucose tolerance or increase plasma glucose. These must be excluded before a definitive diagnosis is made. For example, an individual who has not fasted for a minimum of 8 hours may have an elevated FPG. Patients who are tested for glucose tolerance during, or very soon after, an acute illness (e.g., a myocardial infarction [MI]) or who are on corticosteroids (e.g., prednisone, dexamethasone) may be misdiagnosed because of the presence of high concentrations of counter-regulatory hormones that increase glucose concentrations. Glucose tolerance often returns to normal in these individuals.

LONG-TERM COMPLICATIONS

Although acute hyperglycemic crises can occur in patients with diabetes, the long-term sequelae of diabetes account for most of the morbidity and mortality in the diabetic population. Complications are typically designated as microvascular or macrovascular in nature. Glucose toxicity contributes most to the development and progression of microvascular complications (retinopathy, nephropathy, and neuropathy) owing to the particular susceptibility of these cell systems to elevated glucose.[22] Diabetes is the

---

leading cause of new cases of adult blindness and kidney failure in the United States.[1]

About 60% to 70% of people with diabetes also have some manifestation of peripheral or autonomic neuropathy. Severe peripheral neuropathy coupled with abnormalities in immune function likely contributes to the high rate of lower-extremity amputations among patients with diabetes.[1,23] Finally, poor glucose control promotes development of dental and oral complications and increases the risk of complications during pregnancy for both mother and fetus.[24,25] Macrovascular complications are multifactorial in their etiology and less dependent on hyperglycemia. Diabetes mellitus itself is a well-known risk factor for macrovascular disease (peripheral vascular disease, CVD, stroke). Patients with diabetes have a threefold-to-fourfold elevated risk for MI and cardiovascular death compared with nondiabetic subjects.[26] Insulin resistance and the resultant hyperinsulinemia in Type 2 diabetes mellitus contribute to the development of hypertension, dyslipidemia, and platelet hypersensitivity, all of which then contribute to the increased CVD risk in patients with diabetes.[27] Thus, although tight glycemic control (A1C <7.0%) will dramatically reduce the risk for microvascular disease, its relationship to macrovascular disease is still under intense debate.

RELATIONSHIP OF GLYCEMIC CONTROL TO MICROVASCULAR AND MACROVASCULAR DISEASE

Although epidemiologic studies have shown a general relationship between glucose control and cardiovascular events, recent randomized trials have failed to confirm a benefit of tight glucose control compared with standard control, which highlights the multifactorial nature of macrovascular disease.[28] However, the clear relationship between microvascular events and glycemic control is well established from randomized, clinical trials. The Diabetes Control and Complications Trial (DCCT), and the open-label follow-up trial, DCCT-EDIC (Epidemiology of Diabetes Interventions and Complications), established the benefits of intensive glycemic control on microvascular end points.[29,30] In the DCCT, intensive treatment (A1C 7.1% vs. 9.0%) reduced the risk of clinically meaningful retinopathy, nephropathy, and neuropathy by approximately 60%. The EDIC study was followed as an open-label extension of the DCCT cohorts. Patients originally assigned to the intensive treatment group were shown to have a persistently lower incidence of microvascular complications even after the glucose control reached parity between the two study groups after the end of the randomized portion of the trial.[30,31] The EDIC study also showed a significant reduction in cardiovascular complications among patients previously assigned to the intensive therapy DCCT arm.[32] See Table 53-4 for the glycemic goals of intensive insulin therapy (herein called physiologic or basal-bolus therapy). This persistence of the microvascular benefits of glycemic control has also been demonstrated in patients with Type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS) (see Case 53-11, Question 2).[33]

The relationship between glycemic control and macrovascular disease has always been less clear. Evidence of early atherosclerosis in patients with Type 1 diabetes in whom dyslipidemia and hypertension are typically absent argues strongly for a role of hyperglycemia itself in the development or progression of macrovascular disease.[34] The UKPDS trial was the first to report the benefit of tight BG control on cardiovascular complications in Type 2 diabetes.[35] Although the microvascular benefits were clear, the 21% relative risk reduction for fatal and nonfatal MI and sudden cardiac death failed to reach statistical significance ($p = 0.052$). However, in a planned 10-year follow-up of patients enrolled in the trial, a significant 15% reduction was seen in the risk of MI ($p = 0.01$).[33] A similar finding for macrovascular benefit was reported in a 17-year follow-up of the DCCT-EDIC study.[32] Thus, although glycemic control benefited macrovascular disease, it took more than a decade to see the benefit. Reducing macrovascular risk in patients with diabetes thus takes a more comprehensive approach than just glycemic control. In a trial of multiple risk factor control in Type 2 diabetes, the STENO-2 trial found a significant 53% reduction in macrovascular events with modest control of hypertension, dyslipidemia, and glycemia simultaneously.[36] Control of all major CVD risk factors is highlighted by the ADA for its importance in reducing macrovascular disease risk.[37] See Table 53-5 for the metabolic goals for adults with diabetes.[38,39]

Table 53-4

Goals of Physiologic (Basal-Bolus) Insulin Therapy

Monitoring Parameter	Adults (mg/dL)	School Age (6–12 years) (mg/dL)	Adolescents and Young Adults (13–29 years) (mg/dL)	Pregnancy (mg/dL)
Premeals	80–130	90–130	90–130	60–99
2-hour postprandial plasma glucose	<180	Not routinely recommended	Not routinely recommended	100–129
Bedtime/overnight (2–4 AM) plasma glucose	>70	90–150	90–150	60–99
A1C[a]	<7.0%[b]	<7.5%[c]	<7.5%[c]	<6%
Urine ketones[d]	Absent to rare	Absent to rare	Absent to rare	Rare

See Case 53-2, Question 2, and Case 53-4, Question 2, for discussion. Basal-bolus insulin therapy is a complete therapeutic program of diabetes management and requires a team approach.

[a] A1C, glycosylated hemoglobin, referenced to a nondiabetic range of 4% to 6% using a Diabetes Control and Complications Trial (DCCT)-based assay.

[b] Acceptable values should be individualized to levels that are attainable without creating undue risk for hypoglycemia. These results are similar to the results achieved in the DCCT trial. The American Diabetes Association recommends consideration for a lower goal (e.g., <6%) in individuals with a short duration of diabetes,

long life expectancy, and no significant cardiovascular disease. Less stringent goals may be appropriate for patients with hypoglycemic unawareness, history of severe hypoglycemia, counter-regulatory insufficiency, advanced microvascular or macrovascular complications, or other complicating features (Table 53-10).

[c] A lower goal (<7%) is reasonable if it can be achieved without creating excessive risk for hypoglycemia.

[d] Does not apply to type 2 diabetes patients.

Modified and extrapolated from American Diabetes Association. Standards of medical care in diabetes—2015. Diabetes Care. 2015;38(Suppl 1):S5; American Diabetes Association. Preconception care of women with diabetes. Diabetes Care. 2004;27(Suppl 1):S76; Kitzmiller JL et al. Managing preexisting diabetes for pregnancy: summary of evidence and consensus recommendations for care. Diabetes Care. 2008;31:1060; The Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. N Engl J Med. 1993;329:977.

Three trials published in 2008 and 2009 have raised new questions about tight glycemic control in patients with Type 2 diabetes. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, a higher rate of mortality was seen in the intensive treatment arm, which achieved an A1C of 6.4% compared with the standard arm, which achieved 7.5%.[40] The ACCORD study was a National Heart, Lung, and Blood Institute study of more than 10,000 patients with Type 2 diabetes with known heart disease or multiple cardiovascular risk factors. The intensively treated group had an excess of 3 deaths per 1,000 participants per year compared with the standard group during an average of 4 years on treatment (257 vs. 203 deaths). The higher mortality rate was not attributable to a specific drug therapy or to severe hypoglycemia.[41] A second trial, the Action in Diabetes and Vascular Disease a Controlled Evaluation (ADVANCE), was an even larger study of more than 11,000 patients, which had different findings from ACCORD. In ADVANCE, there was an insignificant trend for reduced cardiovascular mortality and reduced overall mortality with tight glycemic control (A1C of 6.3% compared with 7.0%).[42] Lastly, in the smaller Veterans Affairs Diabetes Trial (VADT), nearly 2,000 patients were studied and found to have an insignificant 12% relative risk reduction in macrovascular end points but a 7% relative increase in overall mortality (95 vs. 102 deaths). Neither finding was statistically significant.[43] After approximately 10-year follow-up to the VADT trial, the study found 1 fewer cardiovascular event/116 person-years without a reduction in mortality. The intensive arm of this study had a mean A1C of 6.9%, not <6.5%.[44]

In the face of these new data, the ADA, along with the American Heart Association (AHA) and the American College of Cardiology (ACC), issued a position statement in 2009.[45] Although acknowledging the findings of the ACCORD trial, the persistent trend for reductions in macrovascular events in all three trials was found to be reassuring. The position of the committee (which continues to be the official position of the ADA in the 2015 guidelines) is that although intensive glycemic control did not improve macrovascular outcomes, a goal of less than 7% is still reasonable based on microvascular benefits and a clear lack of harm across the trials of intensive versus standard glycemic control.[38] However, the ADA does acknowledge that there is room to individualize the A1C goal and that achieving an A1C of less than 7% has limited macrovascular benefit compared with A1C values of 7% to 8%. Patients with Type 2 diabetes and CVD or multiple risk factors for CVD should discuss their treatment goals with their providers. In these patients, a less intensive goal may be appropriate, particularly for patients who have difficulty achieving the goal of less than 7%.[38]

Table 53-5

American Diabetes Association Metabolic Goals for Adults with Diabetes Mellitus[7]

Glycemic goals	
A1C	<7.0% (normal, 4%–6%)[a]
Preprandial plasma glucose	80–130 mg/dL (3.9–7.2 mmol/L)[b]
Postprandial plasma glucose	<180 mg/dL (<10.0 mmol/L)[c]
Blood pressure	<140/90 mm Hg (Refer to Essential Hypertension Chapter 11)
Lipids	Refer to Lipid Chapter 8

Goals must be individualized to the patient. See Case 53-2, Question 2, Case 53-14, Question 2, and Case 53-24, Questions 1–4, for broader discussion.[7]

[a] More stringent goals (i.e., <6%) can be considered for select individuals. American Association of Clinical Endocrinologists/American College of Endocrinology recommends A1C goal of ≤6.5%.[39]

[b] American Association of Clinical Endocrinologists recommends a fasting blood glucose goal of <110 mg/dL (6.1 mmol/L).[39]

[c] American Association of Clinical Endocrinologists/American College of Endocrinology recommends goal of <140 mg/L (7.8 mmol/L).[39]

A1C, glycosylated hemoglobin.

PREVENTION OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

Because the clinical symptoms of Type 1 diabetes mellitus are the overt expression of an insidious pathogenic process that begins years earlier, investigators are focusing attention on strategies that alter the natural history of the disease (Fig. 53-1). First-degree relatives of individuals with Type 1 diabetes mellitus have an increased risk for developing the diabetes and can be identified by the presence of immune markers that may herald the disease by many years.[11] This has led to attempts at immune intervention at the prediabetes stage (primary prevention) or after the development of islet antibodies (secondary prevention). Most immunotherapy trials are tertiary prevention after diagnosis of Type 1 diabetes. Results have not been extraordinary, but will areas of future study. For primary prevention, vaccines, and secondary prevention, immunomodulatory agents will continue to be an area of research.[46] The Diabetes Prevention Program Research Group studied a diverse group of 3,234 individuals at high risk for developing diabetes to determine whether lifestyle interventions or metformin (850 mg by mouth [PO] twice a day [BID]) would prevent or delay the onset of Type 2 diabetes.[47] After 3 years, the incidence of diabetes was reduced by 58% and 31% in the intensive lifestyle and metformin groups, respectively, compared with the control group. Diabetes incidence during 10 years of follow-up was persistently lower in the groups originally treated with lifestyle (34% reduction) and metformin (18% reduction) interventions compared with the control group.[48] Other studies have confirmed the value of lifestyle intervention and other drugs (acarbose, orlistat, and various thiazolidinediones (TZDs)) in the prevention of Type 2 diabetes, but the strongest evidence is with metformin.[49] Lifelong medication therapy, however, is not without its own risks and complications. Current recommendations regarding the treatment for individuals with prediabetes include lifestyle modification (5%–10% weight loss and 150 minutes/week of moderately intense physical activity).[50] Metformin, although less effective than lifestyle changes, can be considered for very high-risk individuals.[49]

CASE 53-1

QUESTION 1: R.P. is a 43-year-old African-American woman visiting a primary-care clinic to obtain a routine physical examination for her new job. Her past medical history is significant for GDM. She was told during her two pregnancies (last child born 3 years ago) that she had “borderline diabetes,” which resolved each time after giving birth. Her family history is significant for Type 2 diabetes (mother, maternal grandmother, older first cousin), hypertension, and CVD. She denies tobacco or alcohol use. She states that she tries to walk 15 minutes twice a week. Physical examination is significant for moderate central obesity (5 feet 4 inches; 160 pounds; BMI, 30.2 kg/m^2) and blood pressure (BP) 145/85 mm Hg. R.P. denies any symptoms of polyphagia, polyuria, or lethargy. On checking her electronic medical record, she has documented hypertension and an FPG value of 119 mg/dL, measured 2 months prior. What features of R.P.’s history and examination are consistent with an increased risk of developing Type 2 diabetes?

The features of R.P.’s history that are consistent with an increased risk of developing Type 2 diabetes include her age, ethnicity, weight, family history of diabetes, history of GDM, and a documented IFG. In addition, Type 2 diabetes is also often associated with other disorders such as hypertension. The fact that R.P. has hypertension that is not well controlled and has a family history of hypertension and CVD may indicate that she is predisposed to insulin resistance, further putting her at risk for developing Type 2 diabetes.

CASE 53-1, QUESTION 2: The physician orders an A1C for R.P., which comes back at 6.1%. How should R.P. be managed at this time?

Both the A1C and FPG values are in the prediabetes range. R.P. should be educated about her risk for developing Type 2 diabetes. Working with her healthcare providers, R.P. should be encouraged and educated on how to institute lifestyle modifications (MNT, physical activity) that will help her to lose weight, improve her cardiovascular health, and decrease her risk for developing Type 2 diabetes. A weight-loss goal of 5% to 10% during the next 6 to 12 months should be recommended, and she should increase her level of moderate physical activity to at least 150 minutes/week. Her hypertension should be managed. At this time, the use of pharmacologic agents (i.e., metformin) to prevent the development of Type 2 diabetes is not recommended.

TREATMENT

There are three major components to the treatment of diabetes: diet, drugs (insulin and antidiabetic agents [oral and injectable]), and exercise. Each of these components interacts with the others to the extent that no assessment and modification of one can be made without knowledge of the other two.

Medical Nutrition Therapy

PRINCIPLES

MNT plays a crucial role in the therapy of all individuals with diabetes.[50,51] Unfortunately, patient acceptance and adherence to diet and meal planning are often poor, but revised evidence-based recommendations that are more flexible than previous approaches offer new opportunities to increase the effectiveness of nutrition therapy.

Nutrition therapy is designed to help patients achieve appropriate metabolic and physiologic goals (e.g., glucose, lipids, BP, proteinuria, weight), select healthy foods, and take into consideration personal and cultural preferences. Appropriate levels and types of physical activity to achieve a healthier status are incorporated into the nutrition plan.

NUTRITION THERAPY AND TYPE 1 DIABETES MELLITUS

For patients with Type 1 diabetes taking fixed doses of insulin, a meal plan is designed to provide adequate carbohydrates timed to match the peak action of exogenously administered mealtime insulin. Regularly scheduled meals and snacks should contain consistent carbohydrate amounts, which are required to prevent hypoglycemic reactions. Fortunately, newer insulins and insulin regimens provide much more flexibility in the amount and timing of food intake. Patients who are taught to count carbohydrates can inject rapid- or short-acting insulin doses designed to match their anticipated intake. Integration of food intake, physical activity, and insulin dose is critical and discussed extensively in the cases that follow.

NUTRITION THERAPY AND TYPE 2 DIABETES MELLITUS

For patients with Type 2 diabetes, meal plans emphasize normalizing plasma glucose and lipid levels as well as maintaining a normal BP to prevent or mitigate cardiovascular morbidity. Although weight loss reduces insulin resistance and improves glycemic control, traditional dietary strategies incorporating hypocaloric diets have not been effective in achieving long-term weight loss. A sustainable weight loss can be achieved within structured programs that emphasize lifestyle changes, physical activity, and food intake that modestly reduces caloric and fat intake.[50,51]

SPECIFIC NUTRITION COMPONENTS

MNT is an integral and critical component of diabetes care. For a more extensive discussion of the principles underlying nutrition therapy, the reader is directed to other sources.[51–53] A few key principles are briefly noted below because they are common sources of misunderstanding.

Carbohydrates and Artificial Sweeteners

Carbohydrates include sugar (sucrose), starch, and fiber and are liberally incorporated into the diet of a person with diabetes. In fact, the amount of dietary carbohydrate is the main determinant of insulin demand and is commonly used to determine the premeal insulin dose. Furthermore, patients using fixed doses of insulin or antihyperglycemic medications (e.g., sulfonylureas) must eat meals containing consistent amounts of carbohydrate to avoid hypoglycemia. Because isocaloric amounts of sucrose and starch produce the same degree of glycemia, sucrose can be substituted for a portion of the total carbohydrate intake and should be incorporated into an otherwise healthful diet.

Whole grains, fruits, and vegetables high in fiber are recommended for people with diabetes, because they are for the general population. There is no evidence that larger amounts produce a differential metabolic benefit with regard to plasma glucose and lipid levels. Nonnutritive sweeteners (saccharin, aspartame, neotame, acesulfame potassium, sucralose) and sugar alcohols have been rigorously tested by the US Food and Drug Administration (FDA) for safety in people with diabetes and are safe at approved daily intakes. Fructose and the reduced-calorie sweeteners called sugar alcohols produce lower postprandial glucose responses than sucrose, glucose, and starch. When sugar alcohols (e.g., sorbitol, mannitol, lactitol, xylitol, and maltitol) are consumed, it is recommended to subtract half of their grams from the total carbohydrate amount because their effect on BG is less. Patients should be advised that when these sweeteners are used in foods labeled “dietetic” or “sugar free,” they still add to the carbohydrate content and provide substantial calories (2 cal/g). Furthermore, excessive intake of sorbitol-sweetened foods (e.g., 30–50 g/day) can induce an osmotic diarrhea, and excessive amounts of fructose can increase total and LDL cholesterol (LDL-C).

Counting Carbohydrates

When patients are taught to estimate the grams of carbohydrate in a meal, they are given the following guideline: One carbohydrate serving = 1 starch or 1 fruit or 1 cup milk = 15 g carbohydrate. Patients vary with regard to their insulin-to-carbohydrate ratio throughout time and throughout the day; however, a typical starting point is 1 unit/15 g carbohydrate.

Fat

CVD is a major cause of morbidity and mortality in patients with diabetes. Therefore, saturated fats should be limited to less than 7% of calories. The intake of trans fat should also be minimized. The recommended cholesterol intake is less than 200 mg/day for patients with diabetes. Two or more servings/week of fish to provide n-3 polyunsaturated fatty acids and omega-3 fatty acids are advised.[50,51]

Protein

Data are insufficient to support special dietary protein recommendations for persons with diabetes if kidney function is normal. Generally, 15% to 20% of the daily caloric intake comes from animal and vegetable protein sources in the US diet. This amount may be liberalized in pregnant and lactating women or in elderly people. With the onset of nephropathy, a lower protein intake of 0.8 to 1.0 g/kg/day is considered sufficiently restrictive. For patients in later stages of nephropathy, reduction of protein intake to 0.8 g/kg/day is recommended. High-protein diets are not recommended as a long-term method for weight loss, because the effects on kidney function are not known.[50,51]

Sodium

The ADA recommends a reduced sodium intake of less than 2,300 mg/day in normotensive and hypertensive individuals. For patients with diabetes and symptomatic heart failure (HF), sodium should be further restricted to less than 2,000 mg/day to help reduce symptoms. For all other patients, the ADA has no particular restrictions on sodium intake, but recommends individualizing amounts based on the patient’s sensitivity to salt and concurrent conditions such as hypertension or nephropathy.[50,51]

Alcohol

The ADA's recommendation for alcohol is consistent with general recommendations of no more than two alcoholic drinks/day for men or one drink/day for women. A drink is equivalent to 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of distilled spirits (each contains about 15 g of carbohydrate). Nevertheless, its caloric contribution must be considered (1 alcoholic beverage = 2 fat exchanges), and it should always be taken with food to minimize its hypoglycemic effect. In people with diabetes, light-to-moderate alcohol intake (one to two drinks/day) is associated with a decreased risk of CVD. A note of caution: Evening consumption of alcohol may increase the risk of nocturnal and fasting hypoglycemia, particularly in people with Type 1 diabetes.[51]

PHYSICAL ACTIVITY

Physical activity is a key factor in the treatment of diabetes, particularly in Type 2 diabetes, because obesity and inactivity contribute to the development of glucose intolerance in genetically predisposed individuals. Regular exercise reduces cholesterol levels, raises HDL-C, lowers BP, augments weight-reduction diets, reduces the dose requirements or need for insulin or antihyperglycemic agents, enhances insulin sensitivity, and improves psychological well-being by reducing stress. Exercise increases glucose utilization, which is provided initially from the breakdown of muscle glycogen and, subsequently, from hepatic glycogenolysis and gluconeogenesis. These effects are mediated through norepinephrine, epinephrine, growth hormone, cortisol, and glucagon, along with the suppression of insulin secretion. In patients using insulin, hyperglycemia, normoglycemia, or hypoglycemia can occur secondary to exercise depending on the degree of control, recent administration of rapid-acting insulin, and food intake. Exercise in patients taking insulin must be tempered by increased food intake, potential delay in insulin administration, decreased doses of insulin, or a combination of these actions to minimize hypoglycemia.[50,51,54,55]

In patients with Type 2 diabetes, plasma glucose concentrations usually decrease in response to exercise, but symptomatic hypoglycemia is uncommon. The vascular benefits of exercise are particularly helpful in patients with diabetes given their predisposition to CVD. In general, exercise that produces moderate exertion (increase in heart rate of 20%–40% from resting baseline) is recommended with a starting goal of 150 minutes/week. The eventual goal is for patients to be able to achieve 50% to 70% of their age-adjusted maximal heart rate.[50]

Resistance exercise has been shown to improve insulin sensitivity. Therefore, in the absence of any contraindications, people with Type 2 diabetes are encouraged to perform resistance training 3 times/week. Patients with conditions that may preclude certain types of physical activity (e.g., coronary artery disease, uncontrolled hypertension, severe autonomic neuropathy, severe peripheral neuropathy or history of foot lesions, and advanced retinopathy in which retinal detachment may occur) should be carefully evaluated before starting an exercise regimen.

Pharmacologic Treatment

Insulin, along with diet, is crucial to the survival of individuals with Type 1 diabetes and plays a major role in the therapy of people with Type 2 diabetes when their symptoms cannot be controlled with diet or noninsulin antidiabetic agents. Insulin also is used for people with Type 2 diabetes during periods of intercurrent illness or stress (e.g., surgery, pregnancy). The use of antidiabetic agents is primarily reserved for the treatment of patients with Type 2 diabetes whose symptoms cannot be controlled with diet and exercise alone. The clinical use of these agents and the complications associated with their use are discussed later in this chapter.

Overall Goals of Therapy

The overall goal of diabetes management is to prevent acute and chronic complications. Periodic assessments of A1C coupled with regular measurement of fasting, preprandial, and postprandial glucose levels should be used to assess therapy. The following overall goals of therapy are agreed on by most endocrinologists:

1. Landmark randomized, prospective trials of various interventional therapies in patients with both Type 1 and Type 2 diabetes have clearly demonstrated that reductions in hyperglycemia significantly decrease microvascular complications. In both the UKPDS and the DCCT follow-up studies, significant reductions in macrovascular complications were also observed. Target BG goals may need to be adjusted for patients with frequent, severe hypoglycemia or hypoglycemia unawareness (see Case 53-8, Questions 1–3, and Case 53-9), or with CVD. In addition, established renal insufficiency, proliferative retinopathy, severe neuropathy, and other advanced complications are not likely to be improved by tight glucose control. See Table 53-5 for the ADA glycemic goals.[38] The American Association of Clinical Endocrinologists and the American College of Endocrinology established glycemic goals as well (Table 53-5).[39] The ADA guidelines will be discussed throughout this chapter.
2. Try to keep patients free of symptoms associated with hyperglycemia (polyuria, polydipsia, weight loss, fatigue, recurrent infection, ketoacidosis) or hypoglycemia (hunger, anxiety, palpitations, sweatiness).
3. Maintain normal growth and development in children. Intensive therapy is not recommended across any age group with a goal A1C of <7.5%. Goals can be individualized, targeting <7% if can be done so safely with minimum hypoglycemia (see Case 53-4, Questions 2 and 3).
4. Eliminate or minimize all other cardiovascular risk factors (obesity, hypertension, tobacco use, hyperlipidemia; see Table 53-5 for glycemic and blood pressure

goals).

5. Try to integrate the patient into the healthcare team through intensive education. The patient's knowledge and understanding of this disease can favorably influence its outcomes (see Table 53-14 later in this chapter).

Methods of Monitoring Glycemic Control

In addition to monitoring signs and symptoms associated with hyperglycemia, hypoglycemia, and the long-term complications of diabetes, an ongoing assessment of metabolic control is an integral component of diabetes management. Ideally, SMBG results combined with laboratory measures of acute and chronic glycemia can be used to evaluate and adjust therapy.[38,56] SMBG and A1C levels continue to be the two primary methods used to access glycemic control. Continuous glucose monitoring (CGM) of interstitial fluid is also available for people with diabetes. CGM is discussed somewhat briefly here because this method is currently recommended for consideration, along with SMBG, for patients with Type 1 diabetes only, especially those with hypoglycemic unawareness.[38,56]

KETONE TESTING

Ketone testing is recommended for patients with gestational and Type 1 diabetes. Urine ketones (acetoacetic acid) should be evaluated when glucose concentrations consistently exceed 300 mg/dL or during acute illness.[56] In addition, a glucose monitor that is able to measure blood β-ketones (e.g., the Precision Xtra has a specific test strip to measure β-hydroxybutyric acid) can be used. Persistently high glucose concentrations of this magnitude signal insulin deficiency that can, in turn, lead to lipolysis and ketoacidosis. A positive test may indicate impending or established ketoacidosis and demands a more extensive diagnostic workup. Testing also is recommended during pregnancy and if the patient has symptoms of ketoacidosis. Although there are generally no ketones in the urine, they may be present in people who are on extremely low-caloric diets and in the first morning sample of women who are pregnant. Also, see discussions of sick day management and ketoacidosis in other sections of this chapter (Cases 53-7 and 53-13).

PLASMA GLUCOSE

FPG concentrations are commonly used to assess glycemic control in the fasting state because this is when glucose concentrations are most reproducible. FPG concentrations generally reflect glucose derived from hepatic glucose production because this is the primary source of glucose in the postabsorptive state. The FPG is the most frequent test performed by patients when self-monitoring. Postprandial glucose concentrations (1–2 hours after the start of the meal) also are used to assess glycemic control when fasting glucose concentrations are within normal limits or when there is a need to assess the effects of food or drugs (e.g., rapid-acting insulins, glinides) on meal-related glycemia. In individuals without diabetes, glucose concentrations generally return to less than 140 mg/dL within 2 hours after a meal. One- to 2-hour postprandial concentrations primarily reflect the efficiency of insulin-mediated glucose uptake by peripheral tissue.

Because glucose concentrations are affected by various factors (e.g., meals, medications, stress), single-time point measurements cannot be used to assess a patient's overall control. Most laboratories measure plasma glucose concentrations rather than whole blood because these values are not subject to changes in the hematocrit. The majority of glucose monitors report plasma-referenced glucose concentrations. Whole BG concentrations are approximately 10% to 15% lower than plasma glucose concentrations because glucose is not distributed into red blood cells.

SELF-MONITORING OF BLOOD GLUCOSE

SMBG has made euglycemia, both preprandially and postprandially, an achievable goal. Patients and their healthcare providers can use SMBG to assess directly the effects of drug dose changes, meals, exercise, and illness on BG concentrations. With improved technology, decreasing costs, and increased coverage by health plans, SMBG is the day-to-day monitoring test of choice for all patients with diabetes. However, SMBG remains expensive for patients without health insurance, is invasive, and can be difficult for some patients to perform depending on their technical ability. Furthermore, to achieve maximal benefit from SMBG, both the clinician and patient must be motivated and willing to spend the time required to interpret the data and modify therapy to improve glycemic control. The frequency and timing of performing SMBG should be dictated by the individual's needs and goals. Selection and use of SMBG testing materials are discussed in Case 53-2, Questions 9 and 10. Patients in whom SMBG is particularly valuable include the following:

- Patients with Type 1 diabetes: Frequent BG measurements help the patient to correlate meals, exercise, and insulin dose with BG concentrations. This instant feedback gives the patient an increased sense of control and motivation, leading to improved glucose control.
- Pregnant patients: Infant morbidity and mortality are associated with the mother's overall glucose control. Using SMBG, the mother with diabetes who achieves normoglycemia before conception and throughout pregnancy improves her chances of delivering a live, healthy infant.
- Patients having difficulty recognizing hypoglycemia: With time, patients with diabetes can develop a sluggish counter-regulatory response to hypoglycemia whereby hypoglycemic symptoms are blunted or even absent. This is often referred to as hypoglycemic unawareness. Routine SMBG to detect asymptomatic

hypoglycemia is essential in these individuals. In addition, acute anxiety attacks or signs and symptoms associated with a rapidly falling BG concentration may mimic a true hypoglycemic reaction. This can be evaluated easily by measuring a fingerstick BG concentration.

- Patients who are using physiologic (e.g., basal-bolus) insulin therapy: Individuals who are on multiple daily doses of insulin or those using an insulin pump should perform SMBG to evaluate the effectiveness of their insulin regimens and meal plans and to check for hypoglycemic or hyperglycemic reactions (see Case 53-2, Question 10). Knowledge of preprandial, postprandial, bedtime, and nocturnal (e.g., 2 AM) BG concentrations is essential in determining basal and preprandial insulin requirements.
- Patients with Type 2 diabetes who are on therapy that can cause hypoglycemia: Individuals taking glinides, a sulfonylurea, or insulin therapy should know how to perform SMBG to detect hypoglycemia when experiencing symptoms consistent with hypoglycemia.
- Patients with Type 2 diabetes who are engaged in self-management of their diabetes: Even individuals using noninsulin therapies can benefit from SMBG to evaluate the impact of food, exercise, and antidiabetic medications on their BG.

CONTINUOUS GLUCOSE MONITORING

Like SMBG, CGM provides real-time information on glucose concentrations. However, the difference is that the CMG system automatically detects glucose concentrations (subcutaneous interstitial fluid glucose concentrations) on a continual basis. CGM systems use electrochemical sensors that are inserted into the skin. Sensor probe length varies as does the duration that the sensor can remain in the skin (3–7 days). The sensors transmit a signal to a receiver (wired or wireless), which records and displays the data every 1 to 5 minutes. The sensors require

a warm-up or initialization period and have very specific calibration requirements. Calibration is performed by using a BG monitor. Interstitial glucose levels lag behind plasma or BG levels by 8 to 18 minutes, depending on the glucose rate of change.[38,57] Therefore, if a person's glucose is low, or trending downward, SMBG is required. CGM systems have alarms that can go off at certain high and low glucose thresholds. The ability to detect hypoglycemia during the night with these alarms has been a very attractive reason for using CGM. Another key feature is the ability to follow trends and rates of change in BG levels. Any acute treatment changes still require SMBG. Small, short-term studies have demonstrated modest improvements in A1C (0.3%–0.6% reductions) in adults and children with Type 1 diabetes.[38] Just as for SMBG with a glucose meter, use of CGM requires a person to actively assess and react to their readings for this self-management tool to have an impact on A1C.

GLYCOSYLATED HEMOGLOBIN

The glycosylated hemoglobin, or A1C, has become the gold standard for measuring chronic glycemia and is the clinical marker for predicting long-term complications, particularly microvascular complications. A1C is most commonly measured because it comprises the majority of A1C and is the least affected by recent fluctuations in BG. A1C measures the percentage of hemoglobin A that has been irreversibly glycosylated at the N-terminal amino group of the β-chain; the plasma glucose level and the life span of a red blood cell (RBC; ~120 days) determine its value. Thus, A1C is an indicator of glycemic control during the preceding 2 to 3 months. In patients without diabetes, A1C comprises approximately 4% to 6% of the total hemoglobin. Values may be 3 times this level in patients with diabetes.[58]

The following formula was developed to convert an A1C into an average glucose: $28.7 \times \text{A1C} - 46.7 = \text{eAG}$ (estimated average glucose). A formula that approximates (not exact) this very closely and is much easier to use in practice is $(\text{A1C} - 2) \times 30$. The ADA now recommends reporting an eAG (units, mg/dL, or mmol/L) along with the A1C. An eAG calculator is available on their website to do this conversion (http://diabetes.org/professional/eAG). The correlation between A1C and eAG is shown in the following table.[59]

A1C (%)	Estimated Average Plasma Glucose (mg/dL)
6	126
7	154
8	183
9	212
10	240
11	269
12	298

Hemoglobinopathies, such as sickle cell trait or chemically modified derivatives of hemoglobin as seen in uremia, in which hemoglobin becomes carbamylated, or acetylated hemoglobin with high-dose aspirin, can affect A1C values (increase or decrease depending on the assay), resulting in inaccurate indications of glycemic control. Alterations in red blood cell survival or turnover, seen in hemolytic anemia and acute blood loss, can falsely lower the A1C. Also a recent blood transfusion or use of intravenous (IV) iron therapy or erythropoietin-stimulating agents in patients with chronic kidney disease can falsely lower A1C values. A glycated serum protein (fructosamine) should be considered for these patients. Antioxidants such as vitamins C and E also may interfere with the glycosylation process.[7,38,60,61]

A1C can be measured without any special patient preparation (e.g., fasting) and generally is not subject to acute changes in insulin dosing, exercise, or diet. A1C values can be used as an adjunct to assess overall glycemic control in patients with diabetes or to diagnose diabetes and prediabetes.[62] Normalization can indicate whether euglycemia has been achieved. However, A1C does not replace the day-to-day monitoring of BG concentrations, which is essential for evaluating acute changes in BG concentrations. These values are needed to adjust the meal plan or medication doses. Sometimes, an A1C is used to verify clinical impressions related to glucose control and patient adherence. It should be measured quarterly in patients who do not meet treatment goals, and at least semiannually in stable patients who are meeting treatment goals.

GLYCATED SERUM PROTEIN, GLYCATED SERUM ALBUMIN, AND FRUCTOSAMINE

Assays for glycated serum proteins reflect the extent of glycosylation of a variety of serum proteins, including glycated serum albumin.[56] The fructosamine assay is one of the most widely used methods to measure glycated proteins (normal, 2–2.8 mmol/L). Because the half-life of albumin is approximately 14 to 20 days, fructosamine provides an indication of glycemic control during a shorter time frame (1–2 weeks) than does the A1C. The ADA does not consider measurement of fructosamine equivalent to that of A1C, although it correlates well with this value. Fructosamine levels may be useful as an adjunct to A1C in determining whether a patient is improving or worsening in the short term (e.g., a patient on insulin therapy undergoing multiple dosage adjustments; for women with Type 2 diabetes during pregnancy or gestational diabetes) or in patients with conditions such as hemolytic anemia in whom the A1C test is inaccurate.

INSULIN

Insulin is a hormone secreted from the pancreatic β-cell in response to glucose and other stimulants (e.g., amino acids, free fatty acids, gastric hormones, parasympathetic stimulation, β-adrenergic stimulation).[63,64] The hormone is made up of two polypeptide chains (a 21-amino acid A chain and a 30-amino acid B chain), which are connected by two disulfide bonds. Proinsulin, the precursor of insulin, is a single-chain, 86-amino acid polypeptide that is processed in the Golgi apparatus of β-cells and then packaged into granules.[63] In the storage granule, the connecting or C-peptide is cleaved from proinsulin to produce equimolar amounts of insulin and C-peptide. Insulin and C-peptide are cosecreted; thus, measurable C-peptide levels indicate the presence of endogenously produced insulin and functioning β-cells. Insulin is crucial to the survival of individuals with Type 1 diabetes, whose β-cells have been destroyed. It also plays a major role in the therapy of many individuals with Type 2 diabetes in combination of antidiabetic agents. Insulin also is used in patients with Type 2 diabetes during pregnancy or periods of illness or stress (e.g., surgery).

Commercially available insulin products differ in their physical and chemical properties as well as in the pharmacokinetics of their action. Prior issues with immunogenicity have been eliminated through modern manufacturing processes and the cessation of use of animal-derived insulin products. Consequently, immunologically mediated sequelae, such as lipodystrophy, hypersensitivity, and insulin resistance caused by “blocking” antibodies, are extremely rare.

Pharmacokinetics: Absorption, Distribution, and Elimination

The route of administration for insulin is primarily via SC injection. Regular insulin, a solution, can be administered by any parenteral route: IV, intramuscularly (IM), or subcutaneously (SC). Most other injectable insulins are only to be used SC with the exception of insulin aspart and insulin lispro which may be used via IV route if they are first diluted. Afrezza (insulin human) is the only insulin currently available as a powder for inhalation. Other routes for insulin administration have been studied, including dermal, nasal, buccal, and oral; however, these formulations are not currently approved for use here in the United States.

After SC injection, insulin is absorbed directly into the bloodstream, bypassing the lymphatic system. The rate-limiting step of insulin activity after SC administration is absorption of insulin from the injection site, which depends on the type of insulin administered, as well as a multitude of other factors. Variations in SC absorption can occur, primarily related to changes in blood flow around the injection site.

Endogenous insulin is secreted directly into the portal circulation and thus is primarily cleared by the liver in nondiabetic individuals (60%), with the kidneys removing only 35% to 40% of it.[63] Exogenous insulin is degraded at both renal and extrarenal (liver and muscle) sites. Degradation also takes place at the cellular level after internalization of the insulin–receptor complex. In contrast to endogenously secreted insulin, up to 60% of exogenous insulin is cleared from the systemic circulation by the kidneys, with the liver accounting for only 30% to 40% of its clearance. Insulin is filtered by glomerular capillaries, but more than 99% is reabsorbed by the proximal tubules. The insulin is then degraded in glomerular capillary cells and postglomerular peritubular cells.[65] See Case 53-6 for changes in insulin requirement in renal dysfunction.

Pharmacodynamics

Clinically, the most important differences among insulin products relate to their onset, peak, and duration of action (not the actual insulin levels, which is pharmacokinetics). Current insulin products can be categorized as rapid-acting, short-acting, intermediate-acting, and long-acting insulin. Products available in the United States are listed in Table 53-6, and the onset of action, peak effect, and durations of action of each insulin category are listed in Table 53-7. However, these data are derived primarily from studies in normal, healthy volunteers in the fasting state or in well-controlled patients with diabetes stabilized in a metabolic ward. In actuality, intersubject and intrasubject variations in response to insulin can be substantial because an individual pattern of response to insulin can be affected by numerous factors (e.g., the formation of insulin hexamers, the presence of insulin-binding antibodies, dose, exercise, site of injection, massage of the injection site, ambient temperature, and interactions between insulins that have been mixed together; see Table 53-8 later in this chapter and Case 53-2, Question 14).[66,67] Nevertheless, knowledge of when one might expect the various insulins to exert their effects is absolutely essential to the rational adjustment of insulin dosages.

Table 53-6

Insulins Available in the United States

Type/Duration of Action	Brand Name	Manufacturer
Rapid Acting		
Insulin lispro	Humalog	Lilly
Insulin aspart	NovoLog	Novo Nordisk
Insulin glulisine	Apidra	Sanofi Aventis
Short Acting		
Regular	Humulin R[a]	Lilly
	Novolin R	Novo Nordisk
Intermediate Acting		
NPH (isophane insulin suspension)	Humulin N	Lilly
	Novolin N	Novo Nordisk
Long Acting		
Insulin glargine	Lantus	Sanofi Aventis
	Toujeo (U-300)	Sanofi Aventis
Insulin detemir	Levemir	Novo Nordisk
Insulin degludec	Tresiba (U-100 and U-200)	Novo Nordisk
Premixed Insulins		
NPH/regular (70%/30%)	Humulin 70/30	Lilly

	Novolin 70/30	Novo Nordisk

Insulin lispro protamine suspension/insulin lispro (75%/25%)	Humalog Mix 75/25	Lilly
Insulin lispro protamine suspension/insulin lispro (50%/50%)	Humalog Mix 50/50	Lilly
Insulin degludec/Insulin aspart (70%/30%)	Ryzodeg 70/30	Novo Nordisk
Inhaled Insulin		
Regular insulin	Afrezza	MannKind

Insulin is made through recombinant DNA technology. Only regular and NPH are human insulin. All other insulins are human insulin analogs. All insulins available in the United States have a concentration of 100 units/mL (U-100), except as noted.

[a] A U-500 concentration is available for use in rare circumstances in patients with severe insulin resistance requiring very large insulin doses.
NPH, neutral protamine Hagedorn, or isophane insulin suspension.

Table 53-7

Insulin Pharmacodynamics

Insulin	Onset (hours)	Peak (hours)	Duration (hours)	Appearance
Rapid-acting (insulin aspart, glulisine, and lispro)	5–15 minutes	30–90 minutes	<5	Clear
Regular	0.5–1	2–4	5–7	Clear
NPH	2–4	4–12	12–18	Cloudy
Insulin glargine U-100	1.5	No pronounced peak	20–24	Clear[a]
Insulin glargine U-300	6	None	24	Clear[a]
Insulin detemir	0.8–2	Relatively flat	5.7–23.2	Clear[a]
Insulin degludec	1	None	42	Clear
Insulin inhalation regular	≤15 minutes	1	3–5	

The onset, peak, and duration of insulin activity may vary considerably from times listed in this table. See text and Table 53-8.

[a] Should not be mixed with other insulins. Some patients require twice-daily dosing.

RAPID-ACTING INSULIN

Insulin Lispro

Insulin lispro (Humalog) was the first available rapid-acting insulin analog. The natural amino acid sequence of the insulin B chain at positions 28 (proline) and 29 (lysine) is inverted to form lispro. This change results in an insulin molecule that more loosely self-associates into hexamers than does regular human insulin. Consequently, the active monomeric form is more readily available, resulting in an onset of activity (15 minutes), peak action (30–90 minutes), and duration (3–4 hours) that more closely simulates physiologic insulin secretion relative to meals. Because it can be injected shortly before eating (0–15 minutes), lispro, and all rapid-acting insulins, provides patients greater flexibility in lifestyle. These insulins lower 2-hour postprandial BG levels and can decrease the risk of late postprandial and nocturnal hypoglycemia compared with regular insulin formulations.[68] Patients who use an insulin pump most often use a rapid-acting insulin instead of regular insulin. One randomized, two-way, crossover, open-label study compared lispro with regular insulin administered for 3 months by continuous SC insulin infusion.[69] Lispro resulted in A1C values that were significantly lower than those produced by regular insulin (7.41% vs. 7.65%). There were no differences in adverse events. Because lispro has a shorter duration of action than regular insulin, hyperglycemia and ketosis may occur more rapidly in patients with Type 1 diabetes if insulin pump delivery is inadvertently interrupted or if the basal insulin dose is missed. Insulin lispro is approved for use in pediatrics (studies included children of age 3 and older), and it is pregnancy category B. Insulin lispro is available in concentrations as both 100 and 200 units/mL. Both formulations are available as an insulin pen (Kwikpen); however, insulin lispro 100 units/mL is available in both vial and insulin pen formulations. The availability of the 200-units/mL formulation allows patients to inject a greater amount of insulin in an overall smaller volume.[70]

Table 53-8

Factors Altering Onset and Duration of Insulin Action

Factor	Comments
Route of administration	Onset of action more rapid and duration of action shorter for IV > IM > SC[87,88]
	Intrapulmonary insulin has onset and duration comparable to SC rapid-acting insulins[89]
Factors altering clearance	
Renal function	Renal failure lowers insulin clearance; may prolong and intensify action of exogenous and endogenous insulin[89]
Insulin antibodies	IgG antibodies bind insulin as it is absorbed and release it slowly, thereby delaying or prolonging its effect[90]
Thyroid function	Hyperthyroidism increases clearance, but also increases insulin action, making control difficult; patients stabilize as they become euthyroid
Factors altering SC absorption	Factors that raise SC blood flow ↑ absorption rates of regular insulin;

<table>
<tr><td></td><td colspan="2">effect on intermediate- and long-acting insulins is minimal</td></tr>
<tr><td rowspan="6">Site of injection</td><td colspan="2">Rate of absorption is fastest from the abdomen, intermediate from the arm, and slowest from the thigh.[88] Less variation is observed in type 2 diabetes patients; less variation is observed with current rapid-acting and long-acting insulins</td></tr>
<tr><td>Site</td><td>Half-life absorption (minutes)</td></tr>
<tr><td>Abdomen</td><td>87 ± 12</td></tr>
<tr><td>Arm</td><td>141 ± 23</td></tr>

Insulin Aspart

Insulin aspart (NovoLog) is a rapid-acting insulin analog that differs from human insulin by substitution of aspartic acid at B28. Insulin aspart is approved for use in pediatric patients, age 2 and older.[71] It is pregnancy category B. Insulin aspart controls postprandial glucose excursions similar to insulin lispro. Insulin aspart is available in both vials and prefilled pen (FlexPen and FlexTouch) formulations.

Insulin Glulisine

Insulin glulisine (Apidra) is a rapid-acting insulin analog that differs from human insulin by substitution of lysine for asparagine at position B3 and glutamic acid for lysine at position B23. Insulin glulisine has been studied in pediatric patients with Type 1 diabetes age 4 and older.[72] It is pregnancy category C. Insulin glulisine lowers postprandial glucose excursions similar to insulin lispro and insulin aspart.

Insulin glulisine is available in both vials and prefilled pen (Solostar) formulations.

Inhaled Insulin

Insulin human powder for inhalation (Afrezza) is a rapid-acting insulin indicated for postprandial coverage in patients with Type 1 or Type 2 diabetes.[73] It is produced using recombinant DNA technology and is supplied via inhaler that is breath-activated by the patient. The insulin in the Afrezza inhaler is regular human insulin, and metabolism and elimination are similar to that of regular insulin following pulmonary absorption. The pharmacodynamic profile of inhaled Afrezza is similar to that of rapid-acting insulin. It is pregnancy category C and has not been studied for use in patients less than 18 years old. Insulin human powder for inhalation is available as prefilled inhalers containing 4, 8, or 12 units of rapid-acting insulin to be used at the beginning of a meal. It is contraindicated for use in patients with chronic lung disease such as asthma and chronic obstructive lung disease as well as current smokers.

SHORT-ACTING INSULIN

Regular insulin 100 units/mL (Humulin R and Novolin R) has an onset of action of 30 to 60 minutes, a peak effect at 2 to 4 hours, and a duration of action of 5 to 7 hours. The broad range in peak effect and duration reflects the many variables that affect insulin action (Table 53-7). The 30- to 60-minute onset of action requires proper timing of premeal regular insulin, which is difficult for most patients. Use of regular insulin in patients with both Type 1 and Type 2 diabetes is much less common with the advent of the newer rapid-acting insulins.

Regular insulin U-500 (500 units/mL) is a concentrated insulin that is indicated for SC only. Being 5 times more potent than the 100 units/mL formulation, it is useful in patients who are severely insulin resistant requiring daily insulin doses of greater than 200 units/day because a large insulin dose may be given in a much smaller volume. Its onset of action is approximately 30 minutes and peaks similar to regular insulin U-100. Regular insulin U-500 however has a longer duration of action (up to 24 hours) compared to the U-100 formulation and is therefore recommended to be administered between 2 and 3 times daily.[74] There are no U-500 insulin syringes available; therefore, to avoid confusion, it is recommended to dose U-500 insulin in volume and administer using a tuberculin syringe vs. a typical U-100 insulin syringe. Additionally, the manufacturer of U-500 regular insulin has incorporated multiple differences in packaging between regular insulin U-100 and U-500 to potentially decrease the risk of dispensing errors. Specifically, the regular insulin U-500 vial contains 20 mL compared to the U-100 vial which contains only 10 mL. The U-500 insulin vial is

---

also marked with a band of diagonal brown stripes to distinguish it from the U-100 vial which contains no stripes.[75] The U-500 insulin pen (Humulin R U-500 KwikPen) approved by the FDA in 2016 should eliminate many of these issues.

INTERMEDIATE-ACTING INSULIN (NPH)

Neutral protamine Hagedorn (NPH) or isophane is an intermediate-acting insulin commercially available as Humulin N or Novolin N. Its onset of action is approximately 2 hours (range, 1–3 hours), peak effects occur at approximately 6 to 14 hours, and the duration of action of NPH is approximately 16 to 24 hours. Again, it must be emphasized that this pattern of response is at best a generalization. Patients may have a variable pattern of response to NPH insulin with time, and those on higher doses are likely to have a later peak and a longer duration of action. Up to 80% of these day-to-day fluctuations in BG responses can be accounted for by variation in the absorption of this intermediate-acting insulin.[66] Novolin N is available only in vials, whereas Humulin N is available both in vials and in prefilled pen (KwikPen) formulations.

LONG-ACTING INSULIN

Insulin Glargine

Insulin glargine U-100 (Lantus) is a long-acting insulin that serves to provide a basal level of insulin. It is pregnancy category C.[76] It is approved for once-a-day SC administration for the treatment of adult and pediatric patients (age ≥6 year) with Type 1 diabetes or adult patients with Type 2 diabetes. It can be administered any time during the day, but it is important to take it at the same time each day. It is usually administered at bedtime or, less commonly, in the morning. Insulin glargine is available in both a 10-mL vial and a prefilled pen (Solostar).

Insulin glargine is an insulin analog in which asparagine in position A21 is substituted with glycine and two arginines are added to the C-terminus of the B chain. This change in the amino acid sequence causes a shift in the isoelectric point from pH 5.4 to 6.7, making it more soluble at an acidic pH.[77] Once injected, insulin glargine (which is a clear solution with a pH of 4.0) precipitates at physiologic pH, forming a depot that releases insulin slowly for up to 24 hours. This results in delayed absorption and a less pronounced peak compared with NPH insulin.[78] Zinc is added to further prolong the duration of insulin glargine. In clinical trials of patients with Type 1 and Type 2 diabetes, once-daily injections of insulin glargine were as effective as NPH in lowering A1C values, with less nocturnal hypoglycemia.[79] Insulin glargine is associated with more injection site pain compared with NPH (6.1% vs. 0.3% in one study and 2.7% vs. 0.7% in another), which is likely related to its acidity.[76,80]

Insulin glargine is also available in a concentrated form which is available as 300 units/mL (Toujeo). It is approved for once-daily SC injection in adults with Type 1 or Type 2 diabetes. Toujeo has not been studied for use in the pediatric population.

Insulin glargine 300 units/mL is only available in a prefilled pen (Solostar device) which does not require dose calculations or conversions when switching from insulin glargine 100 units/mL.[81]

Insulin Detemir

Insulin detemir (Levemir) is another basal insulin available in the United States and is approved for once- or twice-daily SC administration for the treatment of adult and pediatric patients (age ≥2 years) with Type 1 diabetes or adult patients with Type 2 diabetes. It is pregnancy category B.[82] Unlike other insulin analogs, in which the amino acid sequence is modified, for insulin detemir, a fatty acid moiety is added to the last amino acid on the end of the B chain. Insulin detemir is a neutral, soluble insulin preparation in which the B30 threonine has been removed and the B29 lysine residue has been covalently bound to a 14-carbon fatty acid. The result is an insulin that is more slowly absorbed in the SC tissue because the fatty acid moiety binds to albumin, creating a long-acting insulin.[83] Insulin detemir's kinetics and dynamics are dose-dependent.[84] When used in Type 1 diabetes, two injections daily are usually required to provide adequate basal coverage due to a smaller insulin dose requirement in this patient population. Insulin detemir demonstrates less intrasubject variability than NPH or insulin glargine.[85] The clinical significance and impact of this observation are unclear. Insulin detemir is available in both vial and pen (FlexTouch) formulations.

Insulin Degludec

Insulin degludec (Tresiba) is a long-acting basal human insulin analog approved in the United States in 2015 for once-daily SC administration for the treatment of adults with Type 1 or Type 2 diabetes. It is pregnancy category C and is not indicated for use in the pediatric population. Insulin degludec differs from human insulin in that the amino acid threonine in position B30 has been omitted and a side chain consisting of glutamic acid and a C16 fatty acid has been attached.[86] Insulin degludec has a much longer duration of action (>42 hours) compared to other available basal insulins and is available as a prefilled pen (FlexTouch device) in concentrations of both 100 and 200 units/mL. The FDA has also approved a combination insulin degludec/insulin aspart 70/30 combination (Ryzodeg 70/30) which is intended to be used once to twice daily prior to a main meal.

PREMIXED INSULIN

Products that contain premixed NPH and regular insulin in a fixed ratio of 70:30 are available from Lilly as Humulin 70/30 and from Novo Nordisk as Novolin 70/30. Additional premixed formulations are available in which both insulin lispro and insulin aspart have been cocrystallized with protamine to create an intermediate-acting insulin similar to NPH. Humalog Mix 75/25 and Humalog Mix 50/50 (Lilly) are products with lispro protamine and insulin lispro in a fixed ratio of 75:25 and

50:50, respectively. NovoLog Mix 70/30 (Novo Nordisk) is aspart protamine and insulin aspart in a fixed ratio of 70:30. These premixed insulins are useful for patients who have difficulty measuring and mixing insulins and are dosed twice daily. These insulins are compatible when mixed together and retain their individual pharmacodynamic profiles. Each of these mixed insulin combinations is available as both vials and insulin pens with the exception of Novolin 70/30 which is available in insulin vials only (see Table 53-19 later in this chapter and Case 53-2, Question 15).

TREATMENT OF TYPE 1 DIABETES: CLINICAL USE OF INSULIN

Clinical Presentation of Type 1 Diabetes

CASE 53-2

QUESTION 1: A.H., a slender, 18-year-old woman who was recently discharged from the hospital for severe dehydration and mild ketoacidosis, is referred to the Diabetes Clinic from the University Student Health Service (no records available). A fasting and a random plasma glucose ordered subsequently were 190 and 250 mg/dL. Approximately 4 weeks before she was hospitalized, A.H. had moved across the country to attend college—her first time away from home. In retrospect, she remembers that she had symptoms of polydipsia, nocturia (6 times a night), fatigue, and a 12-lb weight loss during this period, which she attributed to the anxiety associated with her move away from home and adjustment to her new environment. Her medical history is remarkable for recurrent upper respiratory infections and three cases of vaginal moniliasis in the past 6 months. Her family history is negative for diabetes, and she takes no medications.

Physical examination is within normal limits. She weighs 50 kg and is 5 feet 4 inches tall. Laboratory results are as follows: FPG, 280 mg/dL; A1C, 14%; and trace urine ketones as measured by Keto-Diastix. On the basis of her history and laboratory findings, the presumptive diagnosis is Type 1 diabetes. Which findings are consistent with this diagnosis in A.H.?

A.H. meets several of the diagnostic criteria for diabetes. She has classic symptoms of Type 1 diabetes (polyuria, polydipsia, glucosuria, fatigue, recurrent infections), a random plasma glucose greater than 200 mg/dL, and a FPG greater than 126 mg/dL on at least two occasions as well as an A1C greater than 6.5%[7] (Tables 53-1 and 53-3). Features of A.H.'s history that are consistent with Type 1 diabetes, in particular, include the relatively acute onset of symptoms in association with a major life event (moving away from home), recent weight loss, ketones in the urine, negative family history, and a relatively young age at onset.[7]

Treatment Goals

CASE 53-2, QUESTION 2: A.H. will be started on insulin therapy on this visit. What are the goals of therapy? Will normoglycemia prevent the development or progression of long-term complications?

The goal of diabetes management is the prevention of acute and chronic complications. The results of the DCCT and DCCT-EDIC studies convincingly demonstrated that lowering BG concentrations through intensive insulin therapy in persons with Type 1 diabetes slows or prevents the development of microvascular complications.[29,30] The ADA recommends an A1C goal of less than 7% for most patients, and an individual goal as close to normal as possible (<6.5%) if it can be achieved without significant hypoglycemia. For children and adolescents, the ADA recommends an A1C goal of less than 7.5%, and an individualized goal of less than 7% if achievable without significant hypoglycemia.[7]

It is important to understand that physiologic or basal-bolus insulin therapy involves a complete program of diabetes management that includes a balanced meal plan, physical activity, frequent SMBG, and insulin adjustments based on these factors (Table 53-4).

In summary, A.H. is a patient newly diagnosed with Type 1 diabetes who has not yet developed any signs or symptoms of long-term complications. Therefore, she is an ideal candidate for basal-bolus insulin therapy, and if she is willing and motivated, normoglycemia with rare hypoglycemic episodes is a reasonable long-term goal. This goal should be achieved gradually over the course of several months with insulin therapy, diet, education, and strong clinical support. A desirable goal is an A1C value as close to the normal range as possible with minimal episodes of hypoglycemia.

Basal-Bolus (Physiological) Insulin Therapy

CASE 53-2, QUESTION 3: What methods of insulin administration are available to achieve optimal glucose control?

A physiologic insulin regimen is designed to mimic normal insulin secretion as closely as possible. Problems with insulin delivery include factors that affect the SC absorption of insulin (Table 53-8).[87,88] Before the development of the rapid-acting insulin analogs and basal insulins, previous insulins lacked pharmacodynamic profiles that allowed one to closely simulate normal pancreatic release of the hormone. In the nondiabetic individual, the pancreas secretes boluses of insulin in response to food. Between meals and throughout the night, the pancreas secretes small amounts of insulin that are sufficient to suppress lipolysis and hepatic glucose output (basal insulin). Clinicians now have more tools to mimic this basal-bolus model. Two methods have been used to achieve this pattern of insulin release: (a) insulin pump therapy (previously referred to as continuous subcutaneous infusion of insulin) and (b) basal-bolus insulin regimens consisting of once- or twice-daily doses of basal insulin coupled with premeal/snackdoses of rapid-acting insulin (see Case 53-2, Questions 3–5).

INSULIN PUMP THERAPY

The use of an insulin pump is currently the most precise way to mimic normal insulin secretion. This consists of a battery-operated pump and a computer that can program the pump to deliver predetermined amounts of insulin (i.e., regular, lispro, aspart, or glulisine) from a reservoir to a SC inserted catheter or needle.[89,90] These systems are portable and designed to deliver various basal amounts of insulin over the course of 24 hours as well as meal-related boluses. Most patients using an insulin pump use a rapid-acting insulin, rather than regular insulin. For meal coverage, the rapid-acting insulin can be given 0 to 15 minutes before eating. The delivery of the bolus can be adjusted depending on the type of food eaten (e.g., piece of cake versus slice of pizza). Caveat: If SC delivery is interrupted, check for rise in glucose and urine ketones after 2 or 3 hours. Because there is no SC pool, effects dissipate quickly.

The preferred meal-planning approach for patients using an insulin pump is carbohydrate counting. The insulin-to-carbohydrate ratio, or how much carbohydrate is covered by 1 unit of insulin, must be determined. One method is to use the "500 Rule." The number 500 (or 450 for regular insulin) is divided by the total daily dose (TDD) of insulin the patient is using to determine the insulin-to-carbohydrate ratio (see Case 53-2, Question 11). Insulin pumps are capable of delivering many basal insulin rates. The basal insulin infusion rate may be adjusted depending on the situation. Many patients find it advantageous to decrease the basal rate during the middle of the night when nocturnal hypoglycemia is most likely to occur. The basal rate also may be increased before awakening to avoid hyperglycemia secondary to the "dawn phenomenon" or adjusted when physically active—adjustments that are not possible using SC basal insulin injections.

Features of the current pump models include the "bolus wizard," which calculates bolus doses based on preset carbohydrate-to-insulin ratios and correction factors, carbohydrate counts for selected foods, and an "insulin-on-board" feature, which helps avoid excessive dosing of insulin by indicating how much insulin from a previously administered dose should still be acting. Most insurance plans provide coverage for insulin pumps for patients with Type 1 diabetes and for some patients with Type 2 diabetes. Factors to consider when choosing a pump include safety features, durability, ability of the manufacturer to provide service, availability of training, clinically desirable features, CGM compatibility, and cosmetic attractiveness for the user.[90,91] The ADA website (www.diabetes.org) contains helpful information about insulin pumps for patients under the Living with Diabetes section.

MULTIPLE DAILY INJECTIONS

CASE 53-2, QUESTION 4: How can insulin be administered to A.H in order to model physiologic release of insulin from the pancreas?

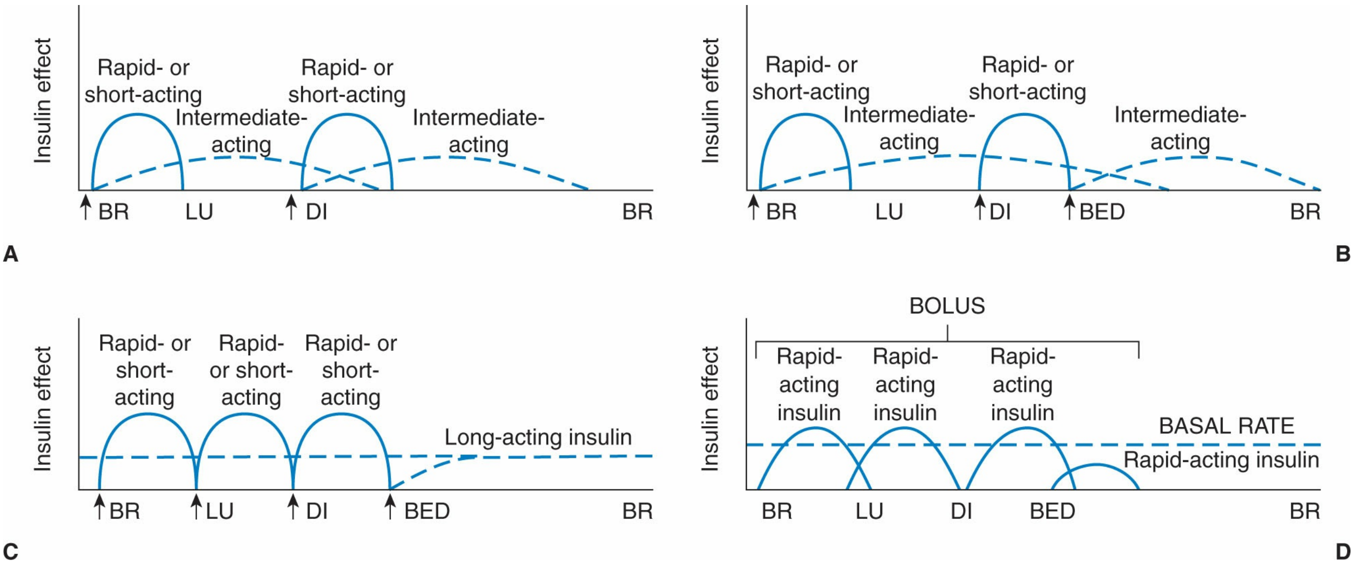

Figure 53-4 Theoretic insulin effect provided by various insulin regimens. **A:** Two daily injections of rapid-acting (insulin aspart, glulisine, or lispro), short-acting (regular), and intermediate-acting insulin (NPH). **B:** Morning injection of rapid-acting or short-acting insulin and intermediate-acting insulin, a predinner injection of rapid-acting or short-acting insulin, and a bedtime injection of intermediate-acting insulin. Suggested for patients with early-morning hypoglycemia, and also those who have early-morning hyperglycemia (owing to rebound phenomenon from hypoglycemia). **C:** Premeal injections of rapid-acting or short-acting insulin and long-acting (e.g., insulin glargine or detemir) or intermediate-acting insulin (NPH) at bedtime. **D:** Continuous subcutaneous insulin infusion, showing an example with bolus given for a bedtime snack. BR, breakfast; Bed, bedtime; LU, lunch; DI, dinner. Arrows indicate time of insulin injection (<15 minutes before meals for rapid-acting insulin and 30 minutes before meals for short-acting insulin).

Endocrinologists have developed a variety of insulin regimens that are intended to mimic the natural release of insulin from the pancreas.[92,93] Examples of these are displayed and illustrated in Figure 53-4. A TDD of insulin is estimated empirically (e.g., 0.3–0.5 units/kg/day for patients with Type 1 diabetes) or according to guidelines listed in Table 53-9. The TDD of insulin then is split into several doses. In general, the basal dose comprises approximately 40% to 50% of the TDD, and the other bolus doses comprise the remaining 50%. If a patient eats three meals/day, the bolus dose would then be divided by three to calculate the number of units of bolus insulin required to cover each meal.

Table 53-9

Empiric Insulin Doses

Estimating Total Daily Insulin Requirements	
These are initial doses only; they must be adjusted using SMBG results. Patients may be particularly resistant to insulin if their blood glucose concentrations are high (glucose toxicity); once glucose concentrations begin to drop, insulin requirements often decrease precipitously. The weight used is actual body weight. Insulin dose requirements can change dramatically with time depending on circumstances (e.g., a growth spurt, modest weight gain or loss, changes in physical activity, stress or illness)	
Type 1 diabetes	
Initial dose	0.3–0.5 units/kg
Honeymoon phase	0.2–0.5 units/kg
With ketosis, during illness, during growth	1.0–1.5 units/kg
Type 2 diabetes	
With insulin resistance	0.7–1.5 units/kg
Estimating Basal Insulin Requirements	
These are empiric doses only and should be adjusted using appropriate SMBG results (fasting or premeal). Basal requirements vary throughout the day, often increasing during the early-morning hours. The basal requirement also is influenced by the presence of endogenous insulin, the degree of insulin resistance, and body weight. Basal requirements are approximately 50% of total daily insulin needs. Thus, basal insulin dose is approximately 50% of TDD. A conservative approach is to reduce the calculated 50% basal dose by 20% to avoid hypoglycemia[93]	
Estimating Premeal Insulin Requirements	
The premeal insulin requirements are approximately 50% of the TDD, usually divided equally into three doses initially, taken with each meal (i.e., breakfast, lunch, and dinner), and then each premeal dose is individually adjusted based on BG readings The “500 rule” estimates the number of grams of carbohydrate that will be covered by 1 unit of rapid-acting insulin. The rule is modified to the “450 rule” if using regular insulin	
500/TDD of insulin = number of grams covered	
Example: For a patient using 50 units/d, 500/50 = 10. Therefore, 10 g of carbohydrate would be covered by 1 unit of insulin lispro, glulisine, or aspart. This equation works very well for type 1 diabetes patients in estimating their premeal insulin requirements. Because patients with type 2 diabetes have insulin resistance, the rule may underestimate their insulin requirements	
Determining the “Correction Factor”	
Supplemental doses of rapid-acting insulin are administered to acutely lower glucose concentrations that exceed the target glucose concentration. These doses must be individualized for each patient and again are based on the degree of sensitivity to insulin action. For example, if the premeal blood glucose target is 120 mg/dL and the patient’s value is 190 mg/dL, additional units of rapid-acting insulin could be added to the premeal dose. The correction factor determines how far the blood glucose drops per unit of insulin given and is known as the “1,700 rule.” For regular insulin, the rule is modified to the “1,500 rule.” The equation is as follows:	
1,700/TDD = point drop in blood glucose per unit of insulin	
Example: If a patient uses 28 units/day of insulin, their correction factor (or insulin sensitivity) would be 1,700/28 = 60 mg/dL. Therefore, the patient can expect a 60-mg/dL drop for every unit of rapid-acting insulin administered. Patients with a higher-sensitivity factor have lower-insulin requirements. Individuals with a lower-sensitivity factor (higher-insulin requirements) typically achieve a smaller reduction in blood glucose per unit of insulin	

SMBG, self-monitored blood glucose; TDD, total daily dose.

Pumping Insulin: Everything You Need For Success On A Smart Insulin Pump. 4th ed. San Diego, CA: Torrey Pines Press; 2006; Walsh J et al. Using Insulin: Everything You Need for Success With Insulin. San Diego, CA: Torrey Pine Press; 2003.

A regimen much less commonly used in patients with Type 1 diabetes involves injecting a mixture of intermediate-acting and regular or rapid-acting insulin twice daily, before breakfast and before dinner (Fig. 53-4A). The morning dose of regular or rapid-acting insulin is intended to take care of the breakfast meal; the morning dose of NPH takes care of the noon meal and provides basal insulin throughout the day; the evening dose of regular or rapid-acting insulin takes care of the evening meal; and the evening dose of NPH provides basal insulin levels during the night and takes care of any evening snack that is ingested. Because NPH is an intermediate-acting insulin and has a peak effect, it does not provide true basal insulin coverage. Also, when NPH is injected in the morning, the patient must eat lunch on time because of this peak effect; otherwise, he/she will experience hypoglycemia. Also, when NPH is taken with mealtime insulin before dinner, the patient is at risk for nocturnal hypoglycemia from the peak effect of the evening dose of NPH. The advantage of using a rapid-acting insulin (e.g., insulin lispro, insulin aspart, or insulin glulisine) instead of regular insulin in this regimen is to facilitate the patient being able to take insulin doses immediately before a meal. However, the peak effect of the NPH component in this combined dose still presents the same problems. This type of insulin regimen does not mimic physiologic insulin release.

Figure 53-4B depicts a variation of this method. It is the same except that the evening dose of NPH is given as a third injection at bedtime. This shifts the time of peak effect from approximately 2 to 3 AM to approximately 7 AM. By administering NPH at bedtime, nocturnal hypoglycemia is reduced, and peak insulin activity occurs when the patient is more likely to be awake and ingesting food. This method may be useful for patients in whom nocturnal hypoglycemia and fasting hyperglycemia are particularly troublesome; however, this regimen also does not mimic physiologic insulin release.

The regimen that most closely mimics physiologic insulin release besides the use of an insulin pump is the use of a once-daily basal insulin such as insulin glargine, detemir, or degludec to provide basal insulin levels throughout the day, along with doses of a rapid-acting insulin (preferred) or regular insulin before meals (Fig. 53-4C depicts the long-acting insulin given at bedtime, but it can be given alternatively in the morning). When smaller doses are used, twice-daily insulin detemir and possibly U-100 insulin glargine will be required for 24-hour coverage.[94–96] Insulins U-100 and U-200 degludec and U-300 glargine will last 24 hours with once-daily dosing. This method theoretically provides insulin similar to the insulin pump: constant basal levels plus small boluses for meals and snacks. In doing so, it offers some of the same advantages of the pump in that it permits some degree of flexibility in the patient's lifestyle. For example, if a patient with diabetes chooses to skip a meal, he/she omits a premeal bolus; if the patient chooses to eat a larger meal than usual, he/she increases the premeal bolus. Similar dose adjustments can be made to accommodate snacks, exercise patterns, and acute illnesses. Alternatives to this regimen are depicted in Table 53-4 where the long-acting insulin is replaced with intermediate-acting insulin for basal coverage and or the rapid-acting insulin is replaced with short-acting insulin for bolus coverage. These options however are not preferred because they do not as closely mimic normal physiologic insulin release.

CASE 53-2, QUESTION 5: Should A.H. use an insulin pump or multiple daily insulin injections?

Indications for basal-bolus insulin therapy are listed in Table 53-10. Patients with Type 1 diabetes should be placed on a basal-bolus insulin regimen. A.H. is an ideal candidate to strive for an A1C goal of less than 6.5%. She is newly diagnosed, has not yet developed the long-term complications of diabetes, and should derive the benefits of normoglycemia. Assuming A.H. will be able to manage a basal-bolus insulin regimen, individualized target BG levels that strive for the best level of glucose control possible without placing her at undue risk for hypoglycemia should be prescribed. She must be willing to test her BG concentrations 4 or more times daily and inject herself 4 times daily or learn about the use and care of an insulin pump. She also must be willing to keep detailed BG and food records and participate in an extensive education program that enables her to adjust her insulin doses based on BG concentrations, physical activity, and the carbohydrate content of her snacks and meals.

Transition to an insulin pump is facilitated by patients being able to attain these skills using multiple daily SC insulin injections before insulin pump initiation. The ADA recommends that the use of insulin pumps be limited to highly motivated individuals under the guidance of a healthcare team trained and knowledgeable in their use. Pumps offer the patient the ability to use multiple basal rates during the 24-hour period and assist with the calculation of bolus and correction insulin doses. Most studies have shown that pump therapy provides equivalent and sometimes better glycemic control than does intensive management with multiple injections.[97,98]

Table 53-10

Basal-Bolus (Physiological) Insulin Therapy: Indications and Precautions

Patient Selection Criteria
Type 1 diabetes, otherwise healthy patients (>7 years of age) who are highly motivated, engaged in diabetes self-management and are able to adhere to a complex insulin regimen. Must be willing to test blood glucose concentrations multiple times daily and inject four doses of insulin daily, on average
Women with diabetes who plan to conceive
Pregnant patients with diabetes (preexisting)
Patients poorly controlled on conventional therapy, 2–3 injections daily (includes type 2 diabetes patients)
Technical ability to test blood glucose concentrations
Intellectual ability to interpret blood glucose concentrations and adjust insulin doses appropriately
Access to trained and skilled medical staff to direct treatment program and provide close supervision

Avoid or Use Cautiously in Patients Who Are Predisposed to Severe Hypoglycemic Reactions or in Whom Such Reactions Could Be Fatal
Patients with counter-regulatory insufficiency β-Adrenergic blocker therapy
Autonomic insufficiency
Adrenal or pituitary insufficiency
Patients with coronary or cerebral vascular disease
(Note: Counter-regulatory hormones released in response to hypoglycemia may have adverse effects in these individuals.)
Unreliable, nonadherent individuals, including those who abuse alcohol or drugs and those with psychiatric disorders

Insulin pumps are particularly useful in patients with frequent, unpredictable hypoglycemia, or marked dawn phenomena (see Case 53-3). Others have described the methods by which insulin doses are established and altered in patients using the insulin pump.[91,99] Because A.H. has just been diagnosed, she should be initiated on a basal-bolus SC insulin therapy. Once she has acquired these skills, she may be considered for pump therapy.

Clinical Use of Insulin

INITIATING INSULIN THERAPY

CASE 53-2, QUESTION 6: How should multiple daily insulin injections be initiated in A.H.?

A conservative TDD of insulin is estimated empirically or according to guidelines similar to those listed in Table 53-9 in newly diagnosed patients and will differ in patients with Type 1 and Type 2 diabetes. Many weight-based empiric dose calculations have been proposed as listed in Table 53-9 for patients with both Type 1 and Type 2 diabetes; however, these regimens are mostly beneficial for patients with Type 1 diabetes because these patients are completely insulin deficient. For patients with Type 2 diabetes, initial basal insulin doses that are weight-based or a starting dose of ~10 units daily are appropriate options based on patient-specific information. Insulin doses would then be adjusted based on HBG levels.[100]

For a basal-bolus insulin regimen, insulin glargine, insulin detemir, or insulin degludec could be used as the basal insulin with bolus doses of a rapid- or short-acting insulin (insulin lispro, insulin aspart, insulin glulisine) given at mealtime. During the initial visit, A.H. needs to learn how to inject her insulin (see Case 53-2, Question 8), how to test her BG (Table 53-11), how and when to test for ketones (either urine or blood), and how to recognize and treat hypoglycemia (Table 53-12). She also needs to understand the importance of meal planning and the relationship between carbohydrate intake and insulin action (Table 53-13). It is very important not to overwhelm A.H. with information on the first visit. One should be particularly sensitive to the psychological impact of this diagnosis on A.H., address her major concerns, and provide only the information that is absolutely essential before the next visit. Between visits, she should be assessed and provided information on an as-needed basis by phone. Table 53-14 lists important areas of patient education.

A reasonable first approach for A.H. is to provide a TDD of 24 units of insulin (~0.5 units/kg). Because 50% of the daily dose should be given as basal insulin with the remainder given as rapid-acting insulin divided into three doses, A.H. would take the following: 12 units of insulin glargine once daily (morning or bedtime) with 4 units of insulin aspart or lispro given approximately 5 to 10 minutes before each meal.[71,100]Alternatively, if insulin detemir is used, the dose would generally be split twice daily (6 units BID) as the duration of action of insulin detemir is typically less than 24 hours when given at such a small dose. Caveat: As A.H.'s glucose concentration returns to normal, glucose toxicity will recede and she may require less insulin.

SELECTING AN INSULIN DELIVERY DEVICE

CASE 53-2, QUESTION 7: What kind of insulin delivery device should be prescribed for A.H.?

Table 53-11

Self-Monitored Blood Glucose Testing: Areas of Patient Education

When and How Often To Test
Technique
How and when to calibrate the glucose monitor
Review all "buttons" and their purposes. Identify battery type. Review cleaning procedures, if applicable
Preparation
1. Calibrate monitor/set code for batch of test strips, if required 2. Insert test strip to turn machine on (some meters require user to turn machine on) 3. Prepare all materials: tissue, strip, and lancet 4. Remember to close the lid of the strip container immediately. Strips exposed to air and moisture deteriorate rapidly 5. Wash hands with warm water. Dry thoroughly. A wet finger causes blood to spread rather than form a drop. Milk the finger from the base to ensure an adequate flow of blood 6. Lance the tip of the finger. Avoid the pads of the finger where nerve endings are concentrated 7. Hold the finger below the heart with the lanced area pointing toward the floor 8. Once a sufficient amount of blood is available, quickly apply blood to designated area of the test strip. Depending on the strip type, the blood sample is placed in an area on the surface of the strip or it is applied to the side of the strip where it is taken up by capillary action
Record Results in a Log Book and Bring to All Clinician Visits. Include relevant information regarding diet or exercise
How To Use Results To Achieve Glycemic Targets; Educate Patients on What To Do With Their Blood Glucose Readings (e.g., adjust their insulin dose; modify their carbohydrate content)

Table 53-12

Hypoglycemia

Definition	
Blood glucose concentration <60 mg/dL: Patient may or may not be symptomatic	
Blood glucose <40 mg/dL: Patient is generally symptomatic	
Blood glucose <20 mg/dL: Can be associated with seizures and coma	
Signs and Symptoms	
Blurred vision, sweaty palms, generalized sweating, tremulousness, hunger, confusion, anxiety, circumoral tingling, and numbness. Patients vary with regard to their symptoms. Behavior can be confused with alcohol inebriation. Patients become combative and use poor judgment	
Nocturnal hypoglycemia: nightmares, restless sleep, profuse sweating, morning headache, morning “hangover.” Not all patients have symptoms during nocturnal hypoglycemia	
Clinical Considerations	
Irregular eating patterns	
↑ Physical exercise	
Gastroparesis (delayed gastric emptying)	
Defective counter-regulatory responses	
Excessive dose of insulin or insulin secretagogues (sulfonylureas, glinides)	
Alcohol ingestion	
Drugs	
Treatment	
Ingest 10–20 g of rapidly absorbed carbohydrate. Repeat in 15–20 minutes if glucose concentration remains less than 60 mg/dL or if patient is symptomatic. Follow with complex carbohydrate/protein snack if mealtime is not imminent	
The following are examples of food sources that provide 15 g of carbohydrate:	
Orange, grapefruit, or apple juice; regular, nondiet soda	1/2 cup
Fat-free milk	1 cup
Grape juice, cranberry juice cocktail	1/3 cup
Sugar	1 tbsp or 3 cubes
Lifesavers	5–6 pieces
Glucose tablets	3–4 tablets
If patient is unconscious, the following measures should be initiated:	
Glucagon 1 mg SC, IM, or IV (generally administered IM in outpatient setting; mean response time, 6.5 minutes)	
Glucose 25 g IV (dextrose 50%, 50 mL; mean response time, 4 minutes)	

IM, intramuscular; IV, intravenous; SC, subcutaneous.

Table 53-13

Interpreting Self-Monitored Blood Glucose Concentrations

Test Time	Target Insulin Dose	Target Meal/Snack
Prebreakfast (fasting)	Predinner/bedtime intermediate-acting or basal insulin	Dinner or bedtime snack
Prelunch	Prebreakfast regular or rapid-acting insulin	Breakfast or mid-morning snack
Predinner	Prebreakfast intermediate-acting insulin or prelunch regular or rapid-acting insulin	Lunch or mid-afternoon snack
Bedtime	Predinner regular or rapid-acting insulin	Dinner
2-hour postprandial	Premeal regular or rapid-acting insulin	Preceding meal or snack
2–3 AM or later	Predinner intermediate-acting insulin or basal insulin if given in AM	Dinner or bedtime snack

Considerations: (a) Assumes a regular meal pattern. For patients who travel, have odd working or sleeping hours, or have irregular meal patterns, these guidelines may not apply. (b) Assumes administration of regular insulin 30 to 60 minutes before meals or rapid-acting insulin 0 to 15 minutes before meals and a normal pattern of insulin response (see Table 53-8 for factors that can alter insulin absorption and response). (c) If prebreakfast concentrations are high, rule out reactive hyperglycemia (Somogyi reaction or posthypoglycemic hyperglycemia). Consider contribution of dawn phenomenon as well. Whenever blood glucose concentrations are high, consider reactive hyperglycemia (excessive insulin doses). (d) Consider accuracy of reported test results: (i) Do they correlate with the glycosylated hemoglobin (A1C) and patient's signs and symptoms? (ii) What is the patient's medication adherence? Could results be fabricated? (iii) Is the patient's technique appropriate? Check timing, adequate blood sample, machine, strips, and calibration (Table 53-11). (iv) Are insulin kinetics altered? (v) What is the carbohydrate content, quality, and regularity of meals?

Table 53-14

Areas of Patient Education

Diabetes: Pathogenesis and the complications
Hyperglycemia: Signs and symptoms
Ketoacidosis: Signs and symptoms (Tables 53-22 and 53-23)
Hypoglycemia: Signs, symptoms, and appropriate treatment (Table 53-12)
Exercise: Effect on blood glucose concentrations and insulin dose (Table 53-19)
Diet: See text. Emphasis placed on carbohydrate counting because the carbohydrate is responsible for 90% of the rise in blood glucose after a meal
Insulins:
Injection technique
Types of insulin
Time action profiles (onset, peak, and duration)
Storage
Stability (look for crystallization and precipitation with NPH insulin)
Therapeutic goals: A1C, fasting, preprandial, and postprandial blood glucose levels, cholesterol, triglyceride, blood pressure (refer to Lipid Chapter 8 and Essential Hypertension Chapter 11)
SMBG testing: Table 53-13
Interpretation of SMBG testing results
Foot care: Inspect feet daily; wear well-fitted shoes; avoid self-care of ingrown toenails, corns, or athlete's foot; see a podiatrist

Sick day management: Table 53-20
Cardiovascular risk factors: Tobacco use, high blood pressure, obesity, elevated cholesterol
Importance of annual ophthalmologic examinations; tests for microalbuminuria; keeping up-to-date with immunizations

A1C, glycosylated hemoglobin; NPH, neutral protamine Hagedorn; SMBG, self-monitored blood glucose.

Insulin delivery is achieved utilizing syringes, prefilled insulin delivery devices (pens), or through oral inhalation. Insulin syringes are plastic, disposable syringes with needles that are extremely fine (typically 30–31 gauge), sharp, and well lubricated to ease insertion. Pen needles and syringes have been improved so that insulin injections are relatively painless if proper technique is used. The lengths of needles are 15/64-inch (6-mm) 5/16-inch (8-mm), or ½-inch (12.7 mm).[100] Research has shown that there is no medical reason why a patient would require use of a needle longer than 4 to 6 mm for insulin administration as skin thickness does not vary between different demographics. Previous thoughts that larger or obese patents require longer needle length for proper insulin administration have been disproven. Manufacturers produce 1-, 0.5-, and 0.3-mL syringes for U-100 insulin. For patients such as A.H., using fewer than 30 units of insulin per injection, the 0.3-mL syringe is preferred for ease of reading the dose markings on the syringe. Insulin syringes are available in 1-unit increments or 0.5-unit increments. One-half-unit increments are useful for pediatric patients and for patients who count carbohydrates, because mealtime insulin doses can be rounded to the 0.5 unit.[101]

Insulin pen devices are also available for injecting insulin. Pen devices are often preferred because they make insulin administration much easier, especially for patients who need to take their insulin doses away from home. They also can increase dosing accuracy. The pens are particularly useful for patients with (a) regimens consisting of multiple daily doses of rapid- or short-acting insulin before meals and snacks (such as A.H.), (b) a fear of needles, (c) impaired visual or dexterity problems, (d) hectic work schedules or lifestyle, or (e) a need to train alternative individuals who administer insulin (e.g., school nurses, siblings). Additionally, studies have shown that use of insulin pen devices vs. vial and syringe insulin administration may result in fewer discontinuations of insulin therapy and improve overall adherence to an insulin regimen.[102,103]

Pens eliminate the need to withdraw insulin, and the insulin dose is dialed up on the device. Pen devices are available as a disposable prefilled pen or a durable pen in which an insulin cartridge is replaced. Most typically used are the prefilled pens which contain a built-in, single-use insulin cartridge. U-100 formulations contain 300 units of insulin, whereas concentrated insulins will contain more units in each device. Pen devices are available to dose insulin in 1-unit (most) and 0.5-unit increments (HumaPen

---

Luxura HD). Pen needles are available in 30-, 31-, and 32-gauge needles and 5/32-inch, (4-mm), 3/16-inch (5-mm), 1/4-inch (6-mm), or 5/16-inch (8-mm) lengths, but there is no medical rationale to use needles longer than 6 mm. Patients are advised to use a new disposable needle for each injection. Unfortunately, limited health insurance coverage and higher copays may deter pen use. A detailed review of pen devices (both insulin and noninsulin) was published in 2014.[104]

For insulin delivery using an insulin pump, see Case 53-2, Questions 3 and 5.

If she elected to use a syringe, a 0.3-mL U-100 insulin syringe with a short needle length should be prescribed for A.H. Subjectively, patients can “feel” the difference between different brands, or they may prefer the “ease of bubble removal,” physical characteristics, or packaging of one syringe over another. If she elected to use an insulin pen, a prefilled pen for insulin glargine and insulin aspart or insulin lispro are available. The shortest possible needle length (4 mm for pen needles and 6 mm for syringes) should be prescribed for A.H.

MEASURING AND INJECTING INSULIN

CASE 53-2, QUESTION 8: How should A.H. be instructed to administer her insulin injections?

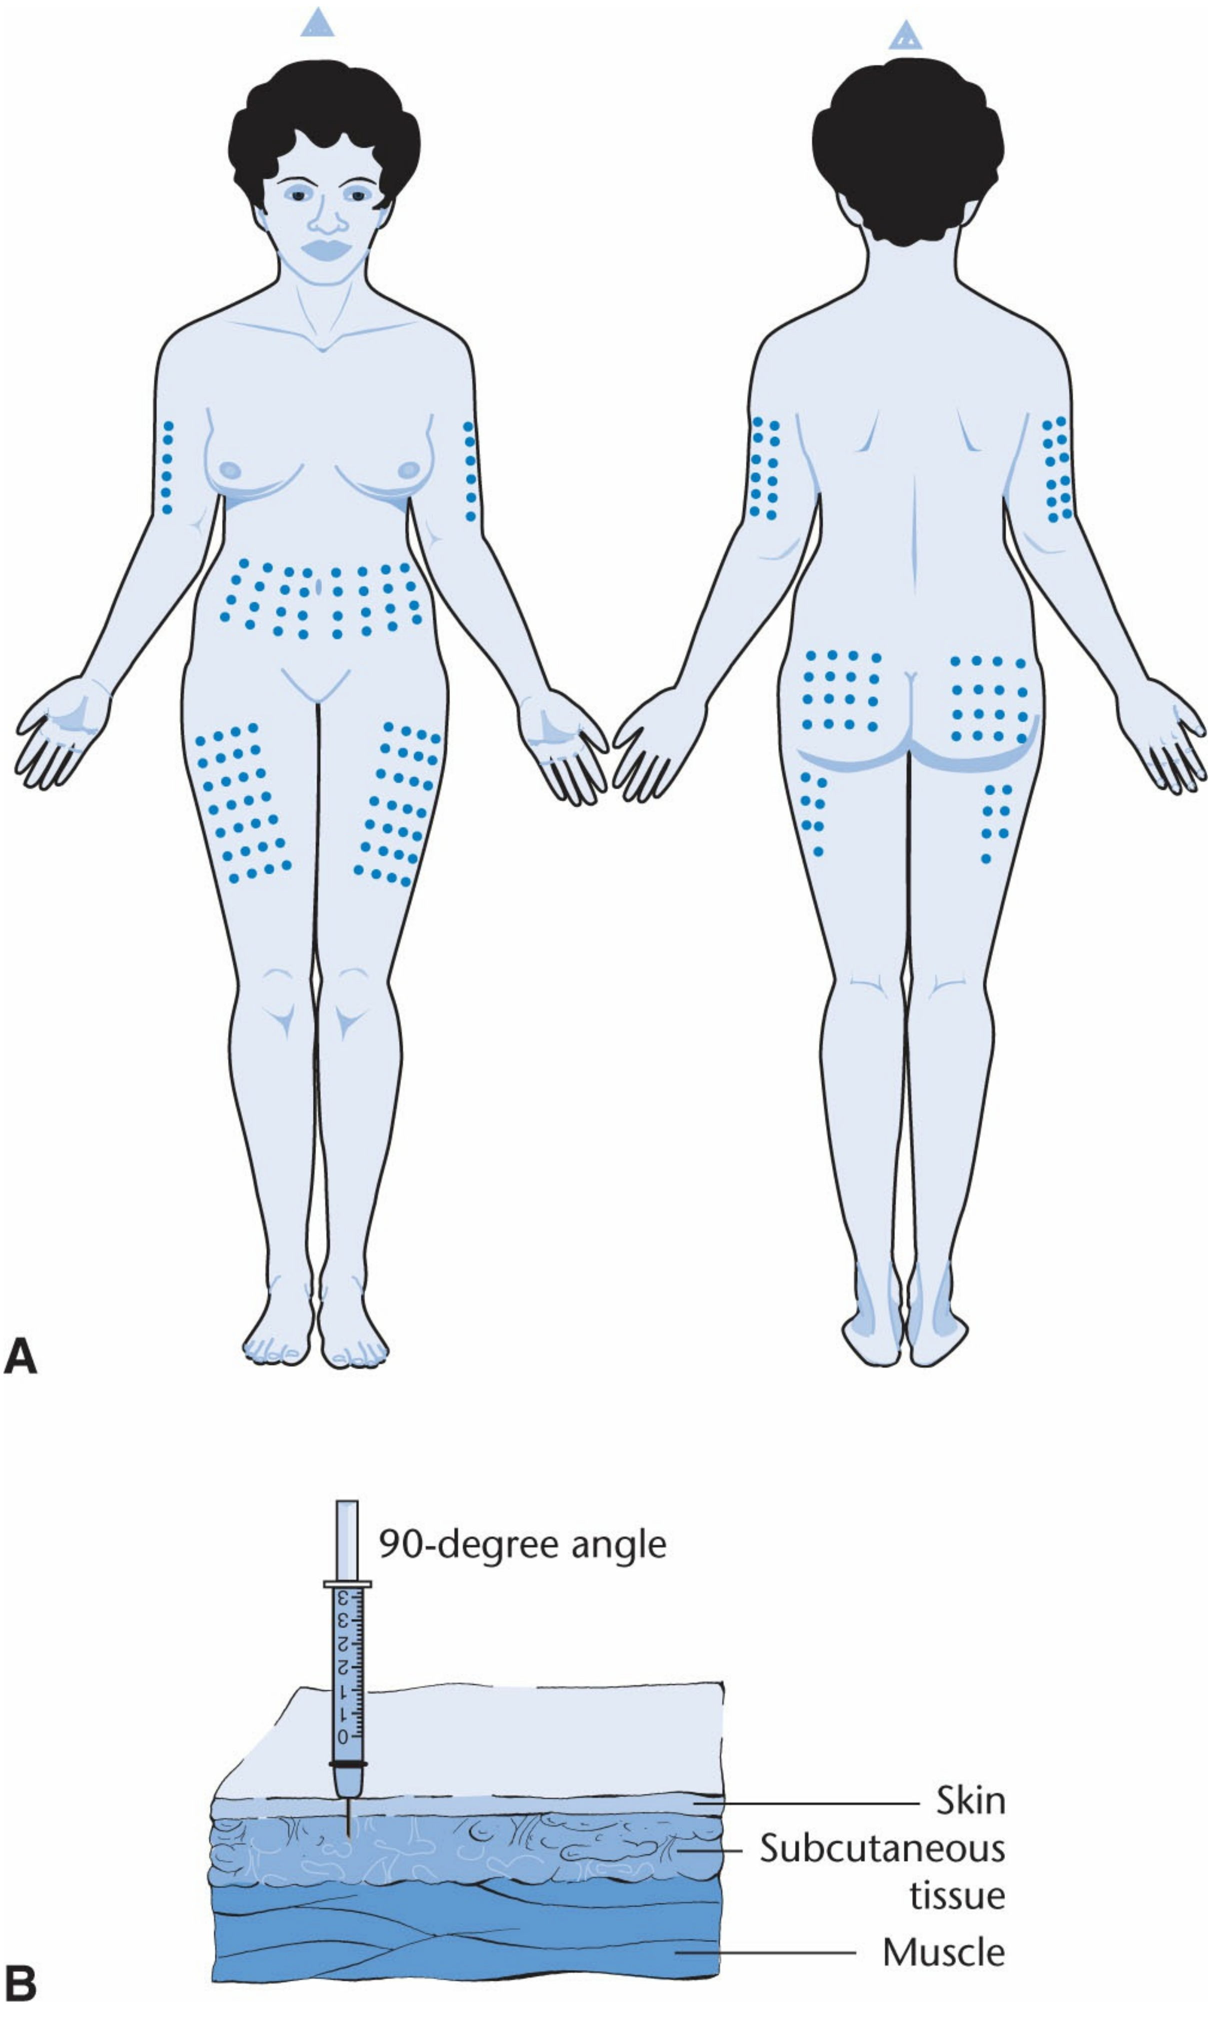
Injection

A.H. should prepare an area for injection. Alcohol swabs may be used to clean the rubber stopper of the insulin vial (or pen device). To inject the insulin SC, A.H. should be instructed to firmly pinch up the area to be injected (this creates a firm surface for the injection) and to quickly insert the needle perpendicularly (90-degree angle) into the center of this area. Note however that if pinching is only necessary then AH is using a syringe that is 6 mm or greater.[101] The syringe should be held toward the middle or back of the barrel, like a pencil. Anxious patients have a tendency to “choke” the hub of the syringe, and this prevents proper needle insertion. A 45-degree angle of injection may be used for infants and very thin individuals who have little SC fat, especially in the thigh area.[101] The site should not be massaged, because this may accelerate the absorption and onset of action of insulin (Table 53-8). When using an insulin pen, the needle should be embedded within the skin for about 5 to 10 seconds after depressing the dosing knob to ensure full delivery of the insulin dose.[101]

Rotating Injection Sites

The primary sites used for injecting insulin are the lateral thigh, abdomen (avoid 2-inch radius around the navel), and upper arm (Fig. 53-5). The ADA recommends that insulin injections be rotated within the same anatomic region to decrease chances of variability in insulin absorption.[101,105] Many practitioners recommend using the abdominal area because absorption from this site is least affected by exercise and is the most predictable. Alternatively, A.H. can be instructed to rotate her morning injection within one region (e.g., the abdomen) and her evening injection in another anatomic region. This minimizes the variables that can alter her response to insulin.

Rotating injection sites also were recommended at one time to avoid the lipodystrophic effect of insulin (lipohypertrophy and lipoatrophy); however, because insulin has been purified, these complications are less common and the importance of rotation is less critical. Nevertheless, repetitive use of the same site of injection may still result in lipohypertrophy, and it does toughen the skin, making needle penetration more difficult. Furthermore, insulin absorption from lipohypertrophic sites can be slowed.[101]



A
B
90-degree angle
Skin
Subcutaneous tissue
Muscle

Figure 53-5 Selecting insulin injection sites. **A:** Areas of the body most suitable for insulin injections. The actual point of injection should be varied each time within a chosen body area. Give injections at least one inch apart. Patients should consult with their provider or diabetes educator about which area is most appropriate for use. **B:** The site where insulin should be injected. Insulin is injected in the subcutaneous tissue (between the skin and the muscle layer). If the skin is pinched up and the needle is pushed all the way in, the need will reach the proper space under the skin. (**A**, LifeART image © 2011. Lippincott Williams & Wilkins. All rights reserved; **B**, Adapted from Springhouse. Lippincott's Visual Encyclopedia of Clinical Skills. Philadelphia: Wolters Kluwer Health; 2009, with permission.)

Agitation

A.H. does not need to agitate insulin glargine or aspart because these are clear insulins. For NPH insulin, which is a suspension, or a combination/mixed insulin, the vial or pen must be gently agitated before use. The vial should be rolled between the palms of the hands to minimize foaming. A pen device is inverted back and forth to mix the insulin. Agitation is only required for insulin suspensions (i.e., insulin mixtures).

Measurement

First, A.H. should make sure her hands and the injection site are clean. She should withdraw the plunger to the level of insulin she intends to inject (e.g., 12 units for her insulin glargine dose), then she should insert the needle into the vial and inject the air to prevent creation of a vacuum within the vial. The vial then should be inverted with the syringe inserted, and 12 units of insulin glargine should be withdrawn. The bevel of the needle should

---

be well below the surface of the insulin to avoid withdrawing air or bubbles into the syringe. Insulin glargine must not be mixed in the same syringe with her rapid-acting insulin, and it should be injected into a different site if it is injected at the same time as her glargine dose.[101]

The barrel of the syringe should be held at eye level to check for air bubbles and to allow accurate placement of the plunger tip at the 12-unit mark. If bubbles are present, they should be removed by tapping the syringe gently to coax the bubbles to the top of the barrel, where they can be injected back into the insulin vial. To remove air bubbles in an insulin pen, prime the pen with 2 units of insulin before each use (repeat until insulin drop appears at tip of pen needle). Also, remove and discard the pen needle from the device in between uses to prevent air bubbles from accumulating.

SELF-MONITORING OF BLOOD GLUCOSE

CASE 53-2, QUESTION 9: How should A.H. be educated to self-monitor her BG? What types of self-monitoring BG tests are available, and what are the major differences among them? How accurate are results obtained from home BG testing? Should she begin CGM at the same time?

The ADA recommends that most individuals with diabetes should attempt to attain and achieve normoglycemia as safely as possible. SMBG is a tool to allow patients to safely achieve these goals. For patients with Type 1 diabetes, this can be achieved by the routine use of SMBG. SMBG is also important in (a) pregnancy complicated by diabetes, (b) patients with unstable diabetes, (c) patients with a propensity to severe ketosis or hypoglycemia, (d) patients prone to hypoglycemia who may not experience the usual warning symptoms, and (e) patients using an insulin pump. The technology in this area is changing rapidly, with new monitors with advanced features being introduced yearly.[90]

All monitors use test strips and are self-timing, requiring no patient action after the blood is placed on the strip. Several factors should be taken into account when evaluating a monitor and its appropriateness for an individual. The primary considerations are ease of use, accuracy relative to a reference standard, reliability, insurance coverage, and cost.[90] Most monitors no longer require coding for the test strips, which simplifies the process for patients. Convenience factors include meter size, volume of blood required for testing, site to obtain sample (e.g., finger versus alternative site such as forearm), capacity of the meter to store BG values (memory) and data such as comments, required testing time, ability to download BG values, general availability of strips, ability to turn off audible signals, audible readings and instructions for visually impaired, and availability of technical support. Some devices are less reliable for use in anemic patients (e.g., renal transplant patients), and all function most reliably within certain temperature ranges (usually 60°F–95°F) and humidity (generally <90%) conditions. Strips are sensitive to light, moisture, and temperature extremes and must be stored and handled with care.

Patient education regarding any testing procedures, the importance of logging results in a diary, and test times are critical. Ultimately, A.H. should be taught how and when to check her BG levels in order to optimize her insulin regimen (Table 53-15).

Table 53-15

Guidelines for Dosing Insulin

Basic Insulin Doses
First, adjust the basic insulin dose (i.e., the dose that the patient will be instructed to take daily)
Only adjust insulin doses if a pattern of response is observed under stable diet and exercise circumstances. That is, the same response to insulin is observed for ≥3 days, particularly for the basal insulin dose. It is important to verify the stability of diet and exercise. Consider adjusting these variables as well
Unless all levels are >200 mg/dL, try to adjust one component of insulin therapy at a time

Start with the insulin component affecting the FBG concentration. This glucose level often is the most difficult to control and often affects all other glucose concentrations measured throughout the day. The basal insulin dose is often what is adjusted to control the FBG. However, if the dinner insulin dose (of rapid-acting or short-acting insulin) is not adequate, this can result in hyperglycemia that can persist into the morning. The basal dose is typically adjusted by 2–4 units, no sooner than every 3–4 days
Prandial/mealtime insulin dose: ■ For patients eating a set amount of carbohydrate at meals: typically adjust the basic insulin dose by 1–2 units at a time. The amount given is based on the individual patient's response to insulin. This can be determined by looking at the patient's total daily dose (TDD) using the "500 rule" (see the following, and Table 53-9) ■ For patients using the insulin-to-carbohydrate method (i.e., 1 unit rapid-acting or short-acting insulin for every x g of carbohydrate), adjust the "ratio" based in the patient's response to insulin (e.g., 1:8, 1:10, 1:12, 1:15, 1:18, 1:20)
General Principles
Assumes that diet and physical activity are stable. Set a reasonable goal initially. This may mean the upper limits of the acceptable concentrations may be high initially (e.g., <200 mg/dL). Move toward a more ideal goal slowly.
Supplementary Insulin Doses (with rapid-acting or short-acting insulin)
Once the basic dose of prandial insulin has been established, supplemental doses of rapid- or short-acting insulin can be prescribed to correct preprandial hyperglycemia. For example, if the goal is 140 mg/dL and the glucose value is 190 mg/dL, administer one additional unit. Supplemental doses also can be used when the patient is ill (Table 53-15)
Algorithms for correction doses are based on the patient's sensitivity to insulin using the "1,500 or 1,700 rule" (Table 53-9)
If premeal glucose concentrations are <60–70 mg/dL, the dose of aspart, glulisine, lispro, or regular insulin administered before the meal is ↓ by 1–2 units; insulin administration is delayed until just before the meal; the meal should include an extra 15 g of glucose if the value is <50 mg/dL
If supplemental doses before a given meal are required for ≥3 days, the basic insulin dose should be adjusted appropriately. For example, if a patient taking lispro before meals requires an extra 2 units before lunch for ≥3 days, 2 units should be added to the prebreakfast dose, or the insulin-to-carbohydrate ratio at breakfast should be adjusted (e.g., if patient was using a 1:15 ratio, a 1:12 ratio could be used). Rapid-acting insulin doses should be adjusted no more frequently than every 2–3 days
Anticipatory Insulin Doses (with rapid-acting or short-acting insulin)
The basic insulin dose is ↑ or ↓ based on the anticipated effects of diet or physical activity ↑ Aspart/glulisine/lispro or regular insulin by 1 unit for each additional 15 g of carbohydrate ingested (e.g., holiday meal) or ↓ the usual dose by 1–2 units if the meal is smaller than usual (Table 53-9)
See Table 53-19 for recommended insulin adjustments for exercise

FBG, fasting blood glucose.

Used properly, available monitors provide reasonably accurate results that can be used by patients to manage their diabetes. Problems with a monitor can be detected by performing a quality-control test once weekly and with each new vial of strips. Table 53-16 lists factors that can affect results of SMBG test results. Any time SMBG values are inconsistent with the patient's symptoms or A1C values, sources of error should be evaluated. A.H.'s technique should be reviewed periodically, because clinical decisions are often based on the patient's BG testing record.

Because A.H. is just starting insulin therapy and SMBG, it would be reasonable to hold off on considering CGM until she becomes comfortable with these skills. Then, she and her practitioner could assess whether CGM would be useful.

TESTING FREQUENCY

CASE 53-2, QUESTION 10: How often should A.H. test her BG concentrations?

Although the exact frequency and timing of BG tests should be dictated by individualized patient goals, most patients with Type 1 diabetes using basal-bolus insulin regimens should perform SMBG at least 3 times daily or more according to the ADA.[38] Glucose monitoring should also be performed more frequently if needed, such as when therapy is modified, prior to exercise, when the patient suspects hypoglycemia, after treatment of hypoglycemia, or when the patient is performing a critical task such as driving. Because A.H. is being initiated on insulin therapy with the goal of normoglycemia, she should ideally self-monitor her BG 4 times/day (before meals and at bedtime) for 2 weeks until the pattern of blood sugar fluctuation can be assessed and adjustments can be made. Motivated patients may continue this degree of monitoring, but it may be reduced to twice daily for patients on long-term insulin. Varying the time of day in which testing is performed will allow the clinician and patient to make informed decisions on how to make adjustments. For those patients who are not using an intensive insulin regimen, such as patients with Type 2 diabetes using insulin, there is insufficient evidence as to how often a patient should check their BG due to the decreased risk of hypoglycemia. Instead patients along with their providers should determine the appropriate frequency and timing to check BG levels in order to best optimize drug therapy and decrease risk for hypoglycemia.[106]

The objective of ongoing, frequent BG testing is to determine whether normoglycemia is being achieved, assess effectiveness of drug therapy as well as the impact of meals, food, illness, or exercise on BG levels. Typical times to check BG may include: before meals and snacks, 2 hours postprandial, at bedtime and occasionally at 2 to 3 AM. However, it can be challenging for patients to adhere to such a rigorous regimen. A.H. should set her alarm for 3 AM 2 or 3 times/week and test her BG. BG concentrations measured before meals allow patients and clinicians to determine whether the rapid-acting insulin dose is appropriate for the amount of carbohydrate consumed; FPG levels are used to determine whether the basal insulin dose is adequate; and the 2 to 3 AM BG level is used to identify nocturnal hypoglycemia. For example, the BG measured before dinner reflects the action of A.H.'s prelunch aspart dose on food she has eaten for lunch, as well as hepatic glucose production between meals. Increasingly, patients who use carbohydrate counting with rapid-acting insulins test 2-hour postprandial levels when initiating therapy to enhance proper dosage adjustment (Table 53-13).

Table 53-16

Factors that Can Alter Self-Monitored Blood Glucose Test Results: Troubleshooting

Glucose monitor not coded for batch of test strips[a]
An inadequate amount of blood applied to test strip[b]
Improper storage of test strips (temperature and humidity)[a]
Dirty glucose monitor[a]
Low battery[a]
Test performed outside of altitude, temperature, and humidity operating conditions[a]
Low[c] or high[b] hematocrit
Dehydration[b]
Hyperosmolar, nonketotic state[b]
Lipemia[a]
Interfering substances

Source: Heinemann L. Quality of glucose measurement with blood glucose meters at the point-of-care: relevance of interfering factors. Diabetes Technol Ther. 2010;12:847.

The importance of frequent BG testing in patients newly diagnosed with Type 1 diabetes cannot be overemphasized. When BG is tested less frequently than 4 times daily, it becomes difficult to adjust insulin doses based on infrequent readings or to assess

---

patterns in glucose levels (i.e., pattern management). If patients refuse to test 4 times daily, they should be encouraged to test 4 times daily on representative days of the week or to test at different times of the day each day so that a weekly profile can be developed. A.H. also should be encouraged to test her BG concentration any time she is feeling unusual, if she is experiencing hypoglycemic symptoms, or to evaluate the effect of unusual circumstances on her BG concentration (e.g., increased physical exercise, a large holiday meal, final examinations, a family crisis).[38]

USING BLOOD GLUCOSE TEST RESULTS TO EVALUATE INSULIN DOSES

CASE 53-2, QUESTION 11: A.H. was instructed to inject herself with 12 units of insulin glargine each evening and to give 4 units of insulin aspart just before each meal. She was asked to test her BG 4 times daily (before meals and at bedtime), to record her results and other unusual events or symptoms during the day, and to bring her BG logbook to the clinic. A.H. was also instructed to track her food and record the number of carbohydrates she ingested at each meal. The initial goal of therapy is to lower her to eliminate symptoms of hyperglycemia. The ultimate goal is to achieve fasting glucoses of 80 to 130 mg/dL and postprandial values of less than 180 mg/dL. One week later, trends in her BG concentrations were as follows:

Time	Glucose Concentration (mg/dL)
7 AM	160–200
Noon	220–260
5 PM	130–180
11 PM	140–180

Occasional 3 AM tests averaged 160 mg/dL, and A.H.'s urine is negative for ketones. She eats approximately four carbohydrate servings for breakfast (60 g) and two to four carbohydrate servings for lunch and dinner (30–60 g). Subjectively, A.H. feels a bit better, and her weight has stabilized, but she still urinates 2 to 3 times nightly. How would you interpret these results, and how should A.H.'s insulin doses be altered?

Values from SMBG appropriately form the basis for insulin adjustments. Ultimately, the goal is to move motivated patients toward being able to recognize their own glucose trends and make insulin adjustments accordingly based on recommendations between the patient and provider.[56] Before using A.H.'s BG results to adjust her insulin dose, it is important to observe and reassess her testing technique. One also should determine whether there were any unusual circumstances in her life such as acute illness, diet changes, drug therapy changes, or exercise patterns during the past week that may have affected her response to insulin. Once these have been ruled out as confounding factors, one can begin making adjustments in A.H.'s insulin dose, realizing that fine-tuning will be impossible until a consistent diet and exercise pattern have been instituted.

Several principles must be kept in mind whenever BG tests are used to adjust a patient's basic insulin dose (Table 53-17). Because many factors can alter a patient's response to insulin, it is important to review BG concentration trends measured for a minimum of 3 days to adjust the basic insulin dose (i.e., the dose the patient will use every day). The only exception to this rule is the use of supplemental insulin doses to correct exceptionally high glucose concentrations after A.H. has acquired sophisticated insulin adjustment skills (see Case 53-2, Question 16). SMBG results should always be evaluated in conjunction with A1C values.

The daily dose of insulin glargine is inadequately controlling A.H.'s FPG and should be increased by 2 to 4 units. A more conservative approach would be to increase the dose to 14 units each evening (or a designated time of day that she will be able to do consistently) and further titrate as needed.[92] She is achieving some response from her lunchtime dose of insulin aspart, but there is room for improvement in her meal insulin coverage overall. The BG concentration of 160 mg/dL at 3 AM indicates that rebound hyperglycemia is an unlikely cause of her high fasting levels (see Case 53-2, Question 13, and Case 53-3). As an initial step toward control, A.H.'s daily dose of insulin glargine should be increased in an attempt to control her fasting hyperglycemia. However, this approach does not address A.H.'s elevated prelunch values. Her intake of carbohydrates also varies from meal to meal. Thus, a more appropriate method would be to calculate the insulin-to-carbohydrate ratio for A.H. and allow her to determine her premeal aspart dose based on the amounts of carbohydrates she will ingest at each meal. A typical starting point for the insulin-to-carbohydrate ratio is 1 unit to every 15 g of carbohydrate ingested. To calculate her insulin-to-carbohydrate ratio, the "500 rule" is used: Divide the number 500 by her TDD of

---

insulin (14 units of insulin glargine plus 12 units of insulin aspart for meal coverage = 26 units):

Table 53-17

Factors that Can Alter Blood Glucose Control

Diet
Insufficient calories (e.g., alcoholism, eating disorders, anorexia, nausea, and vomiting)
Overeating (e.g., during the holidays)
Irregularly spaced, skipped, or delayed meals
Dietary content (e.g., fiber, carbohydrate content)
Physical Activity
See Table 53-19
Stress
Infection
Surgery/trauma
Psychological
Drugs
Certain medications can increase or decrease blood glucose levels. It is important to assess for potential effects on the blood glucose when starting new medications
Hormonal Changes
Menstruation: Glucose concentrations may increase premenstrually and return to normal after menses
Pregnancy
Puberty: hyperglycemia probably related to high growth hormone levels
Gastroparesis

Delays gastric emptying time. Peak insulin action and meal-related glucose excursions may become mismatched
Altered Insulin Pharmacokinetics
See Table 53-8
Insulin Injection Technique
Measuring
Timing
Technique
Inactive Insulin
Outdated insulin
Improperly stored insulin (heat or cold)
Crystallized insulin

$$500/26 = 19 \text{ g of carbohydrate covered by 1 unit of insulin} \qquad \text{(Eq. 53-1)}$$

Because most single servings of carbohydrate contain 15 g, A.H. decides to start with a ratio of 1 unit for every 15 g or single serving of carbohydrates she consumes at each meal. If A.H. were using regular insulin for meal coverage, she could use the "450 rule": 450 divided by the total daily insulin dose yields grams of carbohydrate covered by 1 unit of insulin.

To evaluate the accuracy of her insulin-to-carbohydrate ratio, A.H. will need to check her BG values 2 hours after each meal (postprandial) to assess the appropriateness of her ratio. She agrees to test her BG level 8 times/day and return in 2 weeks.

CASE 53-2, QUESTION 12: A.H. is getting more comfortable with carbohydrate counting and adjusting her insulin doses accordingly. A review of her food diary reveals that for the most part, she is able to determine the appropriate serving sizes for 15 g of carbohydrate. She admits to difficulty determining carbohydrate amounts when eating out. As a result, A.H. notices that her preprandial BG concentrations exceed her goal of 80 to 130 mg/dL on occasion.[7] Sometimes they are as high as 200 mg/dL. Evaluate A.H.'s BG trends. How should occasional preprandial glucose concentrations that exceed the desired goal of 80 to 130 mg/dL be managed?

Once the basal insulin dose and insulin-to-carbohydrate insulin dose have been established, one can begin to teach A.H. how to use a correction factor to adjust her dose of insulin when preprandial BG concentrations fall above or below the range of BG concentrations that have been established as her goal of therapy (80–130 mg/dL per the ADA; Table 53-15).

A correction insulin dose is used to compensate for unusually high BG concentrations (high-sugar correction). To re-emphasize, this assumes there are no unusual changes in the patient's overall diet or exercise patterns (Table 53-18 explains the effects of exercise on BG). Many clinicians favor rapid-acting insulin versus regular insulin because its action is brief and patients do not have to worry about residual effects 3 to 4 hours after its injection. This is particularly valuable when correctional doses of insulin are needed at bedtime.

The patient's sensitivity to insulin, as reflected by his/her TDD on a unit per kilogram basis, is a major determinant of any algorithm developed. A general approach is to give an additional 1 to 2 units of supplemental rapid-acting insulin for each 30- to 50-mg/dL elevation above the target level.[93] An alternative method of estimating the drop in a person's BG per unit of regular insulin is the "1,500 rule."[99] The derived value is referred to as the "sensitivity factor": The rule was modified to the "1,800 rule" for use with rapid-acting insulin (insulin lispro, aspart, or glulisine). Because these insulins tend to drop the BG level faster and farther, 1,500 turns out to be too aggressive. Others have recommended other numerators such as 1,600, 1,700, 2,000, and 2,200.[107] For this case, the "1,700 rule" will be used. The calculation for A.H. would be as follows:

$$1{,}700/24 = 70\ \text{mg/dL} \qquad \text{(Eq. 53-2)}$$

Thus, 1 unit of insulin aspart for A.H. will drop her BG level by about 70 mg/dL. People with a lower-sensitivity factor (higher-insulin requirements) typically achieve a smaller reduction in BG per unit of insulin compared with those with a higher-sensitivity factor (lower-insulin requirement). Thus, an algorithm of 1 unit of insulin aspart for every 70-mg/dL excursion above her goal of 120 mg/dL is a reasonable place to begin. If this dose of insulin is insufficient, one can decrease the BG excursion required per unit of insulin dose (e.g., 50 mg/dL). Correctional insulin doses also are used for sick day management (see Case 53-5). The following is an example of a high-sugar correction algorithm for A.H:

Glucose Concentrations (mg/dL)	**Insulin Aspart**
<80	1 unit less
80–120	Usual dose
120–190	1 unit extra
191–260	2 units extra
261–330[a]	3 units extra
331–400[a]	4 units extra

[a] Check urine or blood ketone levels. If ketones are positive and BG concentrations remain >300 mg/dL for ≥12 hours, call the physician for directions.

Table 53-18

Exercise in Patients with Diabetes

1. Test blood glucose before, during, and after exercise
2. For moderate exercise (e.g., bicycling or jogging for 30–45 minutes), ↓ the preceding dose of regular or rapid-acting insulin by approximately 30%–50%. If glucose concentration is normal or low before exercise, supplement the diet with a snack containing 10–15 g of carbohydrate

3. To avoid ↑ absorption of regular insulin by exercise, inject into the abdomen or exercise 30–60 minutes after injection. Avoid exercise when rapid-acting insulin is peaking
4. Individuals with low glycogen stores may be predisposed to the hypoglycemic effects of exercise. Examples include alcoholics, fasted individuals, or patients on extremely hypocaloric (<800 calories), low-carbohydrate (<10 g/day) diets
5. Patients taking insulin are more susceptible to hypoglycemia than those taking oral insulin secretagogues (sulfonylureas, glinides). Patients with type 2 diabetes treated with diet are unlikely to develop hypoglycemia
6. Watch for postexercise hypoglycemia. Individuals who have been exercising during the day will likely need to ↑ their carbohydrate intake and should test their blood glucose during the night to detect nocturnal hypoglycemia. Hypoglycemia can occur 8–15 hours after exercise
7. If the glucose concentration is >240–300 mg/dL, the patient should not exercise. This indicates severe insulin deficiency. These patients are predisposed to hyperglycemia secondary to exercise
8. Patients with severe proliferative retinopathy or retinal hemorrhage should avoid jarring exercise or exercise that involves moving the head below the waist

EVALUATING FASTING HYPERGLYCEMIA

CASE 53-2, QUESTION 13: A.H. returns after 1 month. She is currently using 14 units of insulin glargine each evening, 1 unit of insulin aspart for each 15 g of carbohydrate ingested at mealtime, and a high-sugar correction factor of 1 unit of insulin aspart for every 70 mg/dL above 130 mg/dL. Presuming that her diet is consistent, her SMBG results are as follows:

Time	Glucose Concentration mg/dL
7 AM	140–180
Noon	120–150
5 PM	90–130
11 PM	90–120
3 AM	60–90

Overall, A.H. feels her diabetes is in good control. Her energy level has returned to normal, and her nocturia has diminished, but she occasionally gets up 1 or 2 times nightly to urinate. A.H. has also noticed that nightmares or "sweats" sometimes awaken her. When this occurs, she generally has something to eat because she is "famished." She is able to get back to sleep, but wakes up the next morning with a "splitting headache" and a "hungover" feeling. A.H.'s weight remains the same, and she has begun to develop some consistency in her dietary patterns with the help of a dietitian. She has been consistently correcting her prelunch and predinner insulin doses by adding or subtracting 2 units from her premeal insulin doses based on her premeal BG values. The A1C from her last visit is 7.3%. Evaluate A.H.'s BG values. What are possible causes of A.H.'s fasting hyperglycemia?

When evaluating morning hyperglycemia, several causes must be considered:

- An insufficient basal dose of insulin. If the basal dose is insufficient, hepatic glucose output during the fasting state will be excessive, thereby producing hyperglycemia.
- Insufficient dinner coverage with insulin aspart, resulting in hyperglycemia that persists into the morning. This can be distinguished from an insufficient basal

insulin by assessing glucose control at bedtime.

- Reactive hyperglycemia in response to a nocturnal hypoglycemic episode (Somog effect or rebound hyperglycemia).
- An excessive bedtime snack.
- The dawn phenomenon (see Case 53-3).

The presence of normoglycemia at bedtime, low BG concentrations at 3 AM, and symptoms of nocturnal hypoglycemia (nightmares, sweating, hunger, morning headache) in A.H. are consistent with a rebound hyperglycemic reaction in the morning (i.e., posthypoglycemic hyperglycemia, also referred to as the Somogyi effect).[108]

Theoretically, this effect occurs after any episode of severe hypoglycemia and is secondary to an excessive increase in glucose production by the liver that is activated by insulin counter-regulatory hormones such as cortisol, glucagon, epinephrine, and growth hormone. The waning effects of the basal insulin dose can also be a cause of fasting hyperglycemia because insulin is needed to suppress hepatic glucose output during the fasting state; however, this is not likely in A.H.'s case. Asymptomatic nocturnal hypoglycemia can occur in patients taking more than necessary doses of insulin in the evening and may potentially cause rebound hyperglycemia in the morning. By correcting the nocturnal hypoglycemia, normalization of A.H.'s fasting hyperglycemia also may be achieved. Thus, a decrease in the daily dose of insulin glargine is warranted. A.H. should continue to monitor her BG concentrations at 3 AM to determine whether her BG levels return to normal.

Caveat: If A.H. were using NPH BID to supply her basal insulin, one option would be to shift the evening injection of NPH from before dinner to bedtime. This preferred method effectively shifts the peak action of NPH to the early morning, when she is awake, and decreases the risk of nocturnal hypoglycemia.[93,109,110] This peak action also corresponds to the dawn phenomenon (see Case 53-3) and the breakfast meal.

Another option if a patient is using NPH and experiencing nocturnal hypoglycemia is to change from NPH to either insulin glargine or insulin detemir because these insulins are associated with less nocturnal hypoglycemia.[111,112] When switching from NPH insulin to insulin detemir, a one-to-one dose conversion may be used although higher doses of detemir may be required. In one crossover study of Type 1 diabetes patients, the average detemir basal dose was approximately double that of the NPH basal dose.[113] However, when switching from NPH insulin to insulin glargine, a one-to-one dose conversion is utilized only when a patient is using NPH insulin once daily. If a patient is taking NPH insulin twice daily, then the total daily insulin dose should be decreased by 20% when switching to insulin glargine. In this case of AH, the daily dose of NPH should be decreased by 20% to determine the insulin glargine dose to err on the conservative side.[76]

Although A.H.'s prelunch BG values are above her goal, this may be attributable to the fasting BG being elevated and then continuing to be elevated mid-morning, like a domino effect. It is important to first correct fasting hyperglycemia and generally correct one BG concentration at a time.

MIXING INSULINS

CASE 53-2, QUESTION 14: If A.H. were to use NPH as basal insulin, how should she be instructed to measure and withdraw this insulin mixture?

Although mixing two insulins in the same syringe has become less common with use of basal-bolus therapy (because insulin glargine and detemir cannot be mixed) and the use of rapid-acting insulin pen devices, the procedure used to mix and withdraw NPH and mealtime insulin (regular or rapid-acting insulin) is basically the same as that described in Case 53-2, Question 8. The major difference is that an adequate volume of air must be injected into the NPH vial before the regular or insulin aspart is measured and withdrawn. Also, the mealtime clear insulin is measured and withdrawn into the insulin syringe first to avoid contamination of the vial of regular, aspart, lispro, or glulisine insulin with NPH. For example, contamination with NPH ultimately alters the NPH to regular insulin ratio that is administered. When patients withdraw NPH insulin first, the vial of regular insulin eventually becomes cloudy. In contrast, contamination of the NPH insulin with regular insulin is insignificant because the protamine contained in NPH can bind the regular insulin (see Case 53-2, Question 15). The procedure A.H. should use to mix her insulins is described in the following section, using her morning dose as an example.

- After dispersing the NPH insulin suspension, inject 14 units of air into the NPH vi and withdraw the needle.
- Inject 7 units of air into the insulin aspart vial, and withdraw the 7 units of insulin described in Case 53-2, Question 8.
- Insert the needle into the NPH vial, and pull the plunger down to the 21-unit mark (14 units of NPH plus 7 units of insulin aspart).

STABILITY OF MIXED INSULINS

CASE 53-2, QUESTION 15: Will mixing NPH with a rapid-acting or regular insulin blunt the rapid action of the mealtime insulins? How stable are other insulin mixtures?

Regular insulin and all of the rapid-acting insulin analogs (aspart, lispro, and glulisine) may be mixed with NPH. In general, it is recommended to mix the insulins just before administration. See Table 53-19 for details on compatibility and stability of insulin mixtures. However, with the increased use of insulin pen devices, mixing of insulins in the same syringe has become a less common practice.

PREMEAL HYPERGLYCEMIA

CASE 53-2, QUESTION 16: After reducing the dose of insulin glargine to 14 units each evening, A.H.'s FPG is now 110 to 125 mg/dL. However, her noon BG concentrations remain in the 120- to 150-mg/dL range. Are there any other changes that you would recommend to make at this time?

Table 53-19

Compatibility of Insulin Mixtures[105]

Mixture	Proportion	Comments
Regular + NPH	Any proportion	The pharmacodynamic profiles of regular and NPH insulin are unchanged when premixed and stored in vials or syringes for up to 3 months
Regular + normal saline	Any proportion	Use within 2–3 hours of preparation
Regular + insulin diluting solution	Any proportion	Stable indefinitely
Rapid-acting + NPH[70–72]	Any proportion	The absorption rate and peak action of the rapid-acting insulins are blunted; total bioavailability is unaltered. Rapid-acting insulin and NPH should be mixed just before use (within 15 minutes)
Insulin glargine and detemir[76,82]	Do not mix with other insulins	Pharmacodynamics could be modified

NPH, neutral protamine Hagedorn.

When evaluating mid-morning hyperglycemia, it is important to remember that the FPG concentration can contribute up to 50% of this plasma glucose excursion. Therefore, a key to the control of mid-morning hyperglycemia may be to normalize the fasting glucose concentration. However, for A.H., the reduction in the insulin glargine has now corrected the reactive fasting hyperglycemia.

Hyperglycemia before a meal can be a result of several factors. The following are possible explanations for A.H.'s mid-morning hyperglycemia:

- An insufficient dose of insulin aspart before breakfast. For A.H., this means that he insulin-to-carbohydrate ratio needs to be adjusted.
- Excessive carbohydrate ingestion at breakfast or inaccurate (under) counting of the carbohydrates ingested. Patients having difficulty accurately counting their carbohydrates should meet with a dietitian or diabetes educator for education; this is often necessary periodically throughout their lives as a refresher, just like many other skills require.
- Poor synchrony between meal intake and insulin action. This could be caused by administration of rapid-acting insulin too long before or after the meal (e.g., ≥30 minutes). If regular insulin is used, this could be caused by administering regular insulin just before or after meals.
- An insufficient dose of evening insulin glargine to suppress hepatic glucose production (glycogenolysis and gluconeogenesis) during the fasting state or the

dawn phenomenon (see Case 53-3). However, in A.H.'s case, her FBG values are in target, so this is not likely.

The following interventions may be considered:

- Adjust her insulin-to-carbohydrate ratio to increase her insulin aspart dose at breakfast. The ratio should be changed to 1 unit of aspart for every 10 or 12 g (which are typical ratios used) of carbohydrate for the breakfast meal. This assumes a patient is technically able to use a different "ratio" at different mealtimes.
- Alter the carbohydrate content of the meals. This may include decreasing the amou of carbohydrate in the breakfast meal, changing the type of carbohydrate ingested, or adding fiber to that meal to minimize glucose excursions.
- Adjust the high-sugar correction factor if the glucose excursions appear to be caus by reduced insulin sensitivity in the morning. For example, the high-sugar correction can be adjusted to give 1 unit of aspart for every 50 mg/dL above 130 mg/dL.

PREPRANDIAL HYPOGLYCEMIA

CASE 53-2, QUESTION 17: A.H. is now taking insulin glargine 12 units each night and using an insulin-to-carbohydrate ratio of 1:15 (1 unit of insulin aspart for every 15 g of carbohydrate) at lunch and dinner and 1:12 at breakfast. She is continuing with the same high-sugar premeal correction of 1 unit of insulin aspart for every 70 mg/dL more than her premeal BG target of 120 mg/dL. Two weeks later, she brings in her BG records.

Time	Glucose Concentration (mg/dL)
7 AM	110–120
Noon	90–115
5 PM	60–110
11 PM	80–110
3 AM	110–120

A.H. feels that she is now "back to normal." She has no signs or symptoms of hyperglycemia, and her weight has remained stable. Occasionally, she becomes hypoglycemic before dinner, but this most often occurs when her dinner is delayed because of a hectic work schedule. Evaluate A.H.'s BG trends. What could be the cause of her predinner hypoglycemia, and how could she be managed?

A.H.'s BG concentrations indicate that her basic insulin regimen is generally adequate to achieve the overall goal of preprandial BG concentrations of less than 80 to 130 mg/dL.

The hypoglycemia A.H. is experiencing before dinner could be caused by insufficient carbohydrate intake at lunch (inaccurate carbohydrate counting), increased activity during the day, or an excessive dose of insulin aspart (insulin-to-carbohydrate ratio too high). Thus, the problem could be resolved by augmenting A.H.'s lunch meal, adjusting the lunch insulin-to-carbohydrate ratio to 1 unit of insulin aspart for every 18 (or 20) g of carbohydrate, or adding a mid-afternoon snack.

DAWN PHENOMENON

CASE 53-3

QUESTION 1: R.D., a 37-year-old man, has had Type 1 diabetes since age 14. During the past 2 years, he has been very well controlled on the following insulin regimen: insulin glargine 20 units each morning with insulin lispro 3 to 4 units depending on carbohydrate intake before meals. On this regimen, his BG concentrations for the past 2 weeks have been as follows:

Time	Glucose Concentration (mg/dL)
7 AM	140–170
Noon	100–120
5 PM	100–130
11 PM	115–140
3 AM	100–120

What are the likely causes of R.D.'s fasting hyperglycemia?

As discussed in Case 53-2, Question 13, fasting hyperglycemia may be the result of insufficient doses of insulin in the evening and, possibly, reactive hyperglycemia. In R.D.'s case, the dawn phenomenon also must be considered.[98] The dawn phenomenon is a rise in the BG concentration that occurs between 4 and 8 AM after a physiologic nadir in the BG concentration that occurs between midnight and 3 AM. This 30- to 40-mg/dL increase in the morning BG concentration cannot be attributed to increases in counter-regulatory hormones secondary to an antecedent hypoglycemic event, but it may be secondary to rising growth hormone levels. This phenomenon is inconsistently observed in individuals with Type 1 and Type 2 diabetes as well as nondiabetic individuals; furthermore, it is inconsistently present from one day to the next.[114]

R.D.'s normal 3 AM BG concentration indicates that posthypoglycemic hyperglycemia is an unlikely cause of his fasting hyperglycemia. Thus, the modest increase in his BG concentration between 3 and 8 AM may be attributed to the waning effects of insulin or the dawn phenomenon. In both cases, an increase in R.D.'s daily dose of insulin glargine would be indicated. Another option would be to switch R.D. to an insulin pump. He has demonstrated a desire and the ability for intensive management with multiple daily injections, frequent SMBG, record-keeping skills, the ability to make appropriate insulin dose adjustments, and accurate carbohydrate counting. The advantage to using a pump is the ability to program an increase in the basal infusion rate in the early-morning hours (e.g., beginning around 2 to 3 AM and continuing until 7 to 9 AM).

Type 1 Diabetes in Children

DIAGNOSIS AND CLINICAL PRESENTATION

CASE 53-4

QUESTION 1: J.C., a 7-year-old, 30-kg (95th percentile), 50 inches tall (90th percentile) girl, was brought to the emergency department by her parents because of nausea, vomiting, and a persistent stomach pain secondary to the flu. For the past week, J.C. had flulike symptoms, resulting in a 6-lb weight loss. Initial laboratory values revealed a BG of 600 mg/dL, serum pH of 6.8 with bicarbonate level of 13 mEq/L, plasma ketone level of 5.2 mmol/L, and positive ketonuria. J.C. was diagnosed with diabetic ketoacidosis (DKA) secondary to new-onset Type 1 diabetes. In retrospect and on further questioning, J.C.'s parents realized that she probably had symptoms as early as 4 weeks before her hospitalization. While on a driving vacation, she drank large quantities of juice and had to stop hourly to urinate. She began experiencing enuresis, which her parents attributed to her increased fluid intake. What signs and symptoms are consistent with the diagnosis of Type 1 diabetes in a child?

The diagnosis of Type 1 diabetes in children is generally straightforward. Presenting symptoms include a several-week history of polyuria, polydipsia, polyphagia, and weight loss, with hyperglycemia, glucosuria, ketonemia, and ketonuria. J.C.'s presentation is typical for a child newly diagnosed with diabetes who is brought in for medical attention because of severe symptoms related to the flu. An acute viral illness can trigger autoimmune destruction of the pancreas and abdominal pain, which may masquerade as gastroenteritis. Abdominal pain is a common presenting symptom of DKA.[115] J.C.'s weight loss probably represents fluid and caloric loss secondary to uncontrolled diabetes as well as decreased caloric intake from the flu. The symptoms of polyuria are less obvious in an infant and are frequently missed until metabolic derangement has occurred. Unlike J.C., infants frequently present with severe dehydration and metabolic acidosis despite a negative history of diarrhea or significant vomiting.

GOALS OF THERAPY

CASE 53-4, QUESTION 2: What are the goals of therapy for J.C.? Do the results of the DCCT apply to children such as J.C.? Are there age-specific goals?

Current ADA guidelines recommend an A1C goal of <7.5% for all pediatric groups and adolescents (<19 years old) such as J.C. with diabetes mellitus. Individualization of goals however is still encouraged.[7]

Additional targets should also be kept in mind, including (a) to achieve normal growth and development, (b) to facilitate positive psychosocial adjustment to diabetes, and (c) to prevent acute and chronic complications. Attainment of these goals requires a tremendous amount of support and education for the parents and can best be provided by a multidisciplinary team of professionals, including a pediatric endocrinologist, nurse educator, pharmacist, dietitian, and mental health professional.[116]

Growth serves as an important clinical indication of overall general health and well-being in children with diabetes. Height and weight should be measured at each visit and plotted on standard growth grids. If, at the time of diagnosis, a child has fallen behind in height or weight, prompt and appropriate treatment should quickly return the child to the appropriate percentile and pattern of growth. An overweight child should be encouraged to achieve a more appropriate percentile of weight gradually, over the course of several months.[117]

Although recommendations for glycemic control are based on data from studies mostly in adult patients with diabetes, achieving the same near-normalization of BG levels in children and adolescents is recommended. However, special consideration must be given to the unique risks and consequences of hypoglycemia in young children. A cohort of adolescents included in the DCCT was analyzed separately.[118] Similar to the adults in the DCCT, adolescents had sustained benefits from intensive management with little further progression to proliferative retinopathy 4 years after the DCCT was terminated.[119] Thus, J.C.'s pediatrician must strive for the best glucose control that she, her family circumstances, and currently available treatment regimens will permit.

The risk of hypoglycemia is of great concern in children younger than 6 years of age as they can have a form of hypoglycemic unawareness that results partly from their reduced capacity to communicate symptoms of hypoglycemia, but may be contributed to by less-developed counter-regulatory mechanisms.[38] In addition, food intake and physical activity are unpredictable in this age group. These factors must be taken into consideration when determining an A1C goal in this patient population where the long-term benefits of achieving a lower A1C need to be weighed against the risk of hypoglycemia.[116] Per the ADA recommendations, the ultimate goal is to achieve the best A1C possible without experiencing symptoms of hypoglycemia. The management of diabetes in children 6 to 12 years of age, such as J.C., is particularly challenging because many children require insulin with lunch or at other times when they are away from home. Administration of insulin at school demands flexibility and close communications between the parents, the healthcare team, and school personnel. (Table 53-4).[38,116,120] The greatest amount of evidence-based data exists for adolescents with diabetes (13–19 years). As mentioned, teenagers included in the DCCT achieved a mean A1C level of 8.06% in an era before the availability of rapid-acting or basal insulins. As stated previously, an A1C goal of less than 7.5% is recommended in this age group.[38,116,120]

INSULIN THERAPY

CASE 53-4, QUESTION 3: How should J.C. be started on insulin? Is the use of an insulin pump appropriate in children such as J.C.?

Generally, rapid-acting and basal insulin analogs are used in children to reduce the risk of hypoglycemia. Insulin requirements are generally based on body weight, age, and pubertal status. Newly diagnosed children with Type 1 diabetes usually require an initial TDD of approximately 0.5 to 1.0 unit/kg.[116] The small insulin requirements of infants and toddlers may be delivered by using diluted insulin (e.g., 10 units/mL, U-10; or 50 units/mL, U-50)[70,71] to measure doses in less than 1-unit increments. Diluents are available for insulin aspart and lispro. Insulin syringes and pens that deliver insulin in 0.5-unit increments are also very useful in pediatric patients. Most children are treated with basal-bolus regimens. These regimens have demonstrated lower FBG levels with less nocturnal hypoglycemia versus regimens using NPH in children and adolescents.[121]

Basal-bolus insulin regimens combined with carbohydrate counting are attractive regimens for middle and high school students. Because children often have erratic eating habits, rapid-acting insulins are advantageous over regular insulin because they can be injected directly before or immediately after a meal, accounting for the portion of the meal a child actually consumed. J.C. should be started on approximately a TDD of 15 units (i.e., 0.5 units/kg/day), such as 3 units of rapid-acting insulin before meals and 7 units of insulin glargine at bedtime.[116,122] In some patients, insulin glargine may not last a full 24 hours; in this case, the dose of insulin glargine should be divided and given twice daily, and then each adjusted based on the BG patterns.[116] Although U-300 glargine or insulin degludec would last 24 hours, they are not FDA-approved in children at this time.

When J.C. and her caregivers become skilled with carbohydrate counting, insulin kinetics, dosing insulin based on her carbohydrate intake, and diabetes management, the use of an insulin pump may be considered. The insulin pump therapy in the pediatric population is increasing rapidly as it provides increased flexibility with meal timing and has been shown to improve glycemic control and quality of life.[123,124] Young children (not just adolescents) are now recommended for consideration of insulin pump therapy.[123] Family and adult support both at home and school is critical for successful pump use until the child is able to manage his/her diabetes independently.

INJECTION SITES

CASE 53-4, QUESTION 4: Where should J.C. administer her insulin? Are the recommended sites of injection different for children? Does the age of the child play a factor?

For infants with abundant SC tissue, injection sites are usually plentiful. For some toddlers who have lost their “baby fat,” locating an appropriate site for injection can be difficult. Injecting insulin into the abdomen of children with minimal SC abdominal fat or in very young children may not be advisable. Rotation of injection sites among arms, thighs, and the upper-outer quadrant of the buttock or hip area, as well as the abdominal area in older children, may be beneficial. To achieve consistent absorption, insulin injections can be patterned, for example, using the arms for the morning injection and the thighs for the evening injection. Children and teens should be cautioned to not consistently inject their insulin into a single area, which may be more convenient for them.[125] Fatty deposits and scar tissue can develop secondary to insulin action at the local tissue level. Insulin absorption from these hypertrophied areas is generally poor and unpredictable, resulting in variability in glycemic control. Insulin pen devices are very helpful for use in children because they are easy to use, have the option for an even smaller needle size, and are less intimidating (see Case 53-2, Question 7).

BLOOD GLUCOSE MONITORING

CASE 53-4, QUESTION 5: How often should J.C. monitor her BG?

The eventual goal for children with diabetes is self-management, with insulin dosing decisions based on interpretation of BG results. Self-management skills and basal-bolus insulin regimens rely on frequent SMBG. For children with Type 1 diabetes, four or more BG tests per day are generally necessary. Many home BG meters allow for alternative site testing (arm or thigh), which decreases the discomfort of fingersticks. Enthusiasm for frequent BG testing tends to wane with duration of diabetes. However, families who are instructed on managing diabetes on the basis of test results are better motivated to persevere with SMBG. CGM may also be considered at some point for improved assessment of her metabolic control, particularly to detect nocturnal hypoglycemia. J.C. should test her BG before each meal and at bedtime, at a minimum. Additional tests should be performed whenever J.C. experiences hypoglycemia, ketonuria, or when she becomes acutely ill.

HONEYMOON PERIOD

CASE 53-4, QUESTION 6: During the next 2 months, J.C.'s insulin requirements decreased to a TDD of 10 units (~0.3 unit/kg). Has her diabetes gone into remission?

Approximately 20% to 30% of individuals with Type 1 diabetes go into a remission phase (honeymoon period) within days to weeks of their diagnosis.[116] During this phase, which can last for weeks to months, insulin requirements can fall well below the usual initial dose of 0.5 to 1.0 units/kg/day, and C-peptide can be detected, indicating a return of pancreatic function. A child may require minimal-to-no basal insulin replacement, and mealtime replacement requirements may need to be reduced. As illustrated by J.C., this presents clinically as markedly decreased insulin requirements to maintain normoglycemia. J.C. should continue to perform SMBG and closely monitor for rising BG concentrations, as β-cell destruction continues during the honeymoon phase and she will eventually return to higher-insulin requirements.

HYPOGLYCEMIA

CASE 53-4, QUESTION 7: J.C.'s parents contacted the clinic to report that J.C. is having nightmares and is awakening in the middle of the night complaining of a headache and stomach pain. However, these symptoms resolve by noon the following day. Her current insulin regimen is insulin aspart 2 units before meals and 3 units of insulin glargine twice daily (at breakfast and bedtime). Could J.C. be experiencing nocturnal hypoglycemia? How do the symptoms of hypoglycemia differ in a child compared with an adult? How can the risk of hypoglycemia be minimized for J.C.?

J.C.'s parents are appropriately worried. Hypoglycemia is a serious and often life-threatening complication of diabetes management in children, and the risk of hypoglycemia increases with attempts to maintain meticulous control of BG levels.[116,126] It was previously thought that pediatric patients may be at risk of cognitive impairment following severe episodes of hypoglycemia; however, current literature does not support this finding. Common causes of hypoglycemia include changes in carbohydrate intake, late or skipped meals or snacks, exercise or unusual activity, and administration of excessive insulin. Because very young children may not be able to identify or express symptoms of hypoglycemia, caretakers must observe the child closely and identify symptoms or behaviors associated with a falling BG. Symptoms of hypoglycemia may include crankiness, sudden crying, restless sleep, or nightmares as seen in J.C.

Hypoglycemia is more frequent in children with lower A1C values, a prior history of severe hypoglycemia, larger insulin doses, and younger children.[127] Nocturnal hypoglycemia is reported in 14% to 47% of children with Type 1 diabetes and is thought to be related to impaired counter-regulatory response to hypoglycemia during sleep.[128] Bedtime BG levels are poor predictors of nocturnal hypoglycemia. J.C.'s parents should be instructed to test her BG at 2 AM closely for the next few nights, and then continue to check at least twice weekly. In children, insulin glargine can exhibit a small peak effect during the initial 3 to 5 hours after administration, increasing the risk for nocturnal hypoglycemia.[116] If this is the case, the insulin glargine dose should be moved to dinnertime or in the morning. If this does not correct the nocturnal hypoglycemia, then the dose should be reduced. Use of insulin glargine is associated with less nocturnal hypoglycemia (and asymptomatic nocturnal hypoglycemia) compared with NPH insulin in children and adolescents.[120,121,129] A bedtime snack may also be needed. Treatment of hypoglycemia is addressed in Case 53-8, Question 3.

SICK DAY MANAGEMENT

CASE 53-5

QUESTION 1: G.M., a 32-year-old woman with Type 1 diabetes, has been well controlled on a basal-bolus regimen (four injections daily) for the past 6 months. However, 2 days ago, she began to exhibit signs and symptoms consistent with the flu. This has made her nauseated, and now she has begun to vomit; consequently, her food intake has been minimal. Because R.D. is not eating at this time, should she discontinue her insulin?

Insulin requirements always increase in the presence of an infection or acute illness, even if food intake is diminished. Patients with Type 1 diabetes, such as G.M., commonly decrease or eliminate insulin doses under these circumstances, and it is in just this setting that ketoacidosis may occur.

Therefore, G.M. should be instructed to maintain her usual dose of insulin and test her BG and urine ketones every 3 to 4 hours. If BG concentrations are above the usual range, extra doses of her rapid-acting insulin should be administered according to a prescribed algorithm based on her body's sensitivity to insulin (e.g., 1 unit for each 50 mg/dL above her BG target). People with Type 1 diabetes should be instructed to test for ketones if their BG concentration is 300 mg/dL or higher. G.M. should call her physician if her BG concentration remains more than 240 mg/dL after three corrective insulin doses; if she has moderate-to-large amounts of ketones in her urine or blood (if using a meter that can measure these); if she has been vomiting or having diarrhea for longer than 6 hours; or if she begins to experience signs and symptoms related to ketoacidosis (polyuria, polydipsia, dehydration, ketonuria, and a fruity breath [see Case 53-10]). G.M. also should attempt to maintain her fluid, mineral, and carbohydrate intake with easily digested food and fluids (Table 53-20).[130]

Table 53-20

Sick Day Management[130]

1. Continue taking your basic dose of insulin even if you are not eating well or have nausea or vomiting
2. Test your blood glucose more frequently: every 3–4 hours
3. If indicated, give yourself extra doses (high-sugar correction) of lispro, aspart, glulisine, or regular insulin: for example, 1–2 units for every 30–50 mg/dL over an agreed-on target glucose concentration (e.g., 150 mg/dL). Correction doses must be individualized based on the patient's sensitivity to insulin (Table 53-9)
4. Begin testing your ketones (urine or blood) if you have type 1 diabetes. If you have type 2 diabetes, begin testing especially when glucose readings exceed 300 mg/dL
5. Try to drink plenty of fluids (½ cup/hour for adults) and maintain your caloric intake (50 g carbohydrate every 4 hours). Foods such as gelatin, noncarbonated soft drinks, crackers, soup, and soda may be used
6. Call a physician if your blood glucose concentration remains >300 mg/dL, or your urine ketones remain high after two or three supplemental doses of insulin, or your blood glucose level remains >240 mg/dL for more than 24 hours

INSULIN REQUIREMENTS IN RENAL FAILURE

CASE 53-6

QUESTION 1: M.B., a 32-year-old woman, has had Type 1 diabetes for 15 years. During the past 2 years, a gradual deterioration of her renal function—as reflected by increased proteinuria, serum creatinine (SCr), and blood urea nitrogen (BUN) values, and reduced glomerular filtration rate (GFR)—has been observed. What are the anticipated effects of decreased renal function on M.B.'s insulin requirements?

The effects of renal failure on insulin requirements are complex, and under various circumstances, insulin requirements may increase or decrease. The kidney is the most important site of extrahepatic insulin metabolism and excretion. In nondiabetic individuals, the liver extracts approximately 60% of insulin secreted endogenously before it reaches the peripheral circulation.[63] Because exogenous insulin is delivered directly to the periphery, the kidneys play a more important role in its elimination. Insulin is filtered by the glomerulus and reabsorbed in the proximal tubules, where it is destroyed enzymatically. The kidney also clears insulin from the peritubular circulation.[65,131] At that site, insulin can enhance the reabsorption of sodium, which may account for the edema occasionally observed after the initiation of insulin therapy in some individuals.

Diminished renal function can be accompanied by decreased clearance of endogenous and exogenous insulin, resulting in increased plasma concentrations of insulin. Therefore, M.B.'s insulin requirements may diminish as her renal disease progresses. Patients with moderate degrees of renal failure (GFR >22.5 mL/minute) remove 39% of insulin from arterial plasma, similar to normal subjects. In contrast, patients with severe renal insufficiency (GFR <6 mL/minute) have a marked reduction in insulin removal from arterial plasma (9%).[132] Decreased insulin clearance in conjunction with nausea and decreased food intake associated with uremia can lead to hypoglycemia in such individuals. In some patients with diabetes, particularly those with residual endogenous insulin secretion (e.g., Type 2 diabetes), glucose tolerance may normalize as renal function diminishes, eliminating the need for insulin. In contrast, severe uremia is associated with glucose intolerance. This seems to be related to tissue resistance to insulin secondary to an unknown factor that can be removed by dialysis.

As M.B.'s renal function worsens, a reduction in her insulin requirements should be anticipated.

MANAGEMENT OF THE HOSPITALIZED PATIENT

CASE 53-7

QUESTION 1: A.G., a 55-year-old, 60-kg woman with a 35-year history of Type 1 diabetes, was admitted to the critical care unit for an abdominal hysterectomy. Before admission, she was well controlled on 24 units of insulin glargine at bedtime and premeal doses of insulin aspart. How should A.G.'s diabetes be managed while in the critical care unit?

Patients with diabetes account for more than 1 in 5 hospital days in the United States. Of the nearly $176 billion that is spent annually on diabetes, nearly half is spent on inpatient care.[8] A clear, linear relationship exists between hyperglycemia and adverse clinical outcomes in the hospitalized patient.[133] However, this relationship exists regardless of a baseline diagnosis of diabetes at the time of admission, and iatrogenic hyperglycemia in the hospital does not have the same relationship morbidity that spontaneous hyperglycemia does.[133–135] These observations have raised important questions about the relationship between hyperglycemia and morbidity in the hospitalized patient.

Complex responses to acute illness including excess secretion of catecholamines and cortisol result in peripheral insulin resistance and so-called stress hyperglycemia. This makes it difficult to discern whether glycemia is a marker or a mediator of adverse outcomes in the acutely ill patient. Accordingly, historic practice had been to only aim for BG concentrations that prevent glucosuria (<200 mg/dL) and the subsequent risk for dehydration in the hospitalized patient. However, beginning in 2001, a series of randomized trials tested glycemic control in the critically ill patient. Significant changes have subsequently been made to practice recommendations for both the critically and the noncritically ill hospitalized patient.

Although several trials beginning in the 1990s tested intensive insulin regimens in patients with acute MI, they were small, placebo-controlled studies and reached different conclusions that proved difficult to rectify.[136–139] In 2001, the first of the van den Berghe trials tested two different levels of glycemic control in a relatively large number of surgical intensive care unit (ICU) patients with hyperglycemia with or without known diabetes.[140] A liberal glucose control strategy (reduction only if BG rose above 215 mg/dL) was compared with normalization of BG (80–110 mg/dL). Overall, normalization of BG significantly reduced ICU mortality from 8.0% to 4.5%.[140] However, the same researchers were unable to replicate their findings in a subsequent, similarly designed study in medical ICU patients with substantially higher baseline mortality rates.[141] Although a substudy showed that an ICU stay of 3 days or longer was predictive of benefit from tight control, a subsequent and much larger trial not only failed to confirm that finding but found increased mortality from a blood sugar of 80 to 110 mg/dL compared with 140 to 180 mg/dL (27.5%, 829 of 3,010 vs. 24.9%, 751 of 3,012).[142] The incidence of severe hypoglycemia (<40 mg/dL) in the different study groups assigned to tight control was between 7% and 18% and did not explain the different findings between studies. However, several important differences between these trials, which helped to inform current guidelines, should be noted.

The 2001 van den Berghe trial used parenteral nutrition in all patients and allowed for higher glucose values (insulin started if blood sugar exceeded 215 mg/dL) to occur in the conventional glycemia arm.[140] It is therefore possible that the aggressive insulin therapy in the tight control group helped to blunt the excessive glucotoxicity that may have been occurring from the parenteral nutrition. In the second van den Berghe trial as in the NICE-SUGAR study, parenteral nutrition was rarely used and initiation of insulin therapy in the conventional arms began at blood sugar values greater than 180 mg/dL.[141] Additionally, in NICE-SUGAR, a more aggressive target of less than 180 mg/dL was used rather than 180 to 200 mg/dL as in the two van den Berghe studies.[140–142] Table 53-21 summarizes these three trials assessing level of glucose control in critically ill patients.

Overall, numerous individual studies as well as meta-analyses have reached different conclusions regarding whether or not tight control of BG is superior to conventional control in the hospitalized, acutely ill patient.[143,144]

In 2009, the ADA made substantial changes to its 2005 guideline on management of inpatient hyperglycemia. Although existing randomized trials of glycemic control have been performed in critical care settings, the ADA guideline included non-ICU settings. To make recommendations for non-ICU patients, ADA relied on case series and retrospective analyses, which will ultimately need to be subjected to randomized, prospective trials.[145–147] In the meantime, recommendations for both critically ill and noncritically ill hospitalized patients are the same: a premeal or fasting BG target less than 140 mg/dL and random values of less than 180 mg/dL. A tighter goal of 110 to 140 mgl/dl however may be beneficial in specific subgroups of patients, such as open-heart surgery patients.[145–148]

Table 53-21

Summary Data of Three Major Trials of Intensive vs. Conventional Glycemic Control with Insulin in Critically Ill Patients

		Glucose Target (mg/dL)		Glucose Achieved (mg/dL)		Primary Outcome	End Point	OR (95% CI)
Trial	**N**	**Intensive**	**Conventional**	**Intensive**	**Conventional**			
van den Berghe et al.[140]	1,548	80–110	180–200	103	153	ICU mortality	4.6% vs. 8%	0.58 (0.38–0.78)
van den Berghe et al.[141]	1,200	80–110	180–200	111	153	Hospital mortality	37.3% vs. 40.0%	0.94 (0.84–1.06)
NICE-SUGAR[142]	6,104	81–108	<180	115	145	90-day mortality	27.5% vs. 24.9%	1.14 (1.02–1.28)

CI, confidence interval; OR, odds ratio.

For perioperative insulin needs, A.G. should receive her usual basal insulin dose (insulin glargine 24 units) on the night before surgery. If the basal insulin is normally administered in the morning, the usual dose can still be given for patients with Type 1 diabetes; for those with Type 2 diabetes, 50% to 100% of the basal insulin is administered the morning of surgery. Correction doses of rapid-acting insulin can be administered the morning of surgery if the BG is more than 180 mg/dL.[149] If a current A1C is not available, it can be measured to assess the patient's glycemic control before admission.

Most insulin infusion protocols include the use of IV regular insulin and maintenance IV fluids, either 5% dextrose in water (D5W) or D5W with 0.45% normal saline (0.45% NaCl). For a patient requiring fluid restriction, 10% dextrose in water (D10W) may be used.[149] The adjustment algorithms are used by nursing to change the rate of infusion (in units/hour) depending on the BG level. Most often, the insulin infusion is prepared in a solution of 1 unit/1 mL normal saline (e.g., 100 units of regular insulin in 100 mL of 0.9% NaCl). A dedicated IV line is used for the insulin infusion to avoid iatrogenic hypoglycemia. The insulin infusion is connected to the maintenance IV containing dextrose (can be Y-connected). Because insulin binds to plastic, the insulin solution should be flushed (e.g., with 20 mL) through the IV tubing before the line is connected to the patient. An IV dextrose infusion is maintained while a patient is on an insulin infusion. Most patients need 5 to 10 g of glucose per hour (or D5W or D5W/0.45% NaCl at 100–200 mL/hour). Additional maintenance fluids (and electrolytes) can be administered via a different port or line. Some protocols include an initial bolus dose of insulin. The initial insulin infusion rate is primarily based on current BG level and BMI; other factors such as body weight, current daily insulin requirements, and renal function should be taken into consideration. An initial rate of 1 unit/hour is common (can range from 0.5 units/hour to ≥2 units/hour). The choice of initial infusion rate is not critical but should be based on patient history. A rate of 0.5 units/hour is appropriate for a patient who has never previously received insulin, whereas 2 units/hour would be appropriate for a patient with known insulin-dependent diabetes. Adjustments in the insulin infusion rate are determined by BG levels every 60 minutes until the BG is stable and close to target. Then, the frequency of BG testing may be reduced to every 2 to 3 hours. Algorithms should consider both the current and previous BG level, the rate of change of the BG level, and the current infusion rate.[38]

Insulin infusion should be started at least 2 to 3 hours before the surgery to titrate to the desired level of glucose control. Examples of protocols are available on the Institute for Healthcare Improvement's website (available at http://www.ihi.org/IHI/Topics/PatientSafety/MedicationSystems/Tools/), and many are published in the medical literature.[150,151]

Thus, A.G.'s usual SC insulin regimen should be discontinued, and she should be initiated on an insulin infusion that is adjusted according to an algorithm. Throughout the perioperative period, she should receive a minimum of 100 g of glucose daily to prevent starvation ketosis.

Assessment of interfering substances with point-of-care BG testing is particularly important for hospitalized patients. Some immunoglobulins and dialysates contain nonglucose sugars (including maltose, xylose, and galactose), which can interfere with glucose measurements with glucose dehydrogenase pyrroloquinolinequinone test strips (will falsely elevate the reading, Table 53-16). BG concentrations should only be performed by the laboratory in these patients.[152]

Adverse Effects of Insulin

HYPOGLYCEMIA

CASE 53-8

QUESTION 1: G.O., a 42-year-old, slightly overweight (5 feet 11 inches, 200 pounds, BMI 27.9 kg/m^2) man, has had a history of Type 1 diabetes mellitus for 17 years. G.O.'s medical care was sporadic until 1 year ago when he referred himself to a diabetes clinic because he was beginning to experience pain and numbness in his feet. At that time, he was poorly controlled on a single daily dose of a premixed NPH and regular insulin mixture (Humulin 70/30), 45 units. He had not been testing his BG concentrations, and his A1C was 13%.

On physical examination, G.O. was found to have an elevated BP (160/94 mm Hg), background retinopathy, and decreased pedal pulses bilaterally. He had decreased sensation to vibration and monofilament testing in both feet. G.O. also complained of impotence and "shooting pains" in both legs. A spot collection for microalbuminuria was 450 mg of albumin/g creatinine (normal, <30 mg/g creatinine).[38]

G.O. was transitioned to a basal-bolus insulin regimen. His physician gave him a premeal BG target of 80 to 130 mg/dL.[38] For the past several months, he has been treated with the following regimen: 14 to 18 units of insulin glulisine before breakfast; 14 to 18 units of insulin glulisine before lunch; 16 to 18 units of insulin glulisine before dinner; and 40 units of insulin glargine at bedtime. If his BG level is high after lunch, he takes additional glulisine (~2 hours after eating). If his BG is high at bedtime (e.g., >150 mg/dL), he takes additional insulin glulisine (7–10 units) because his physician told him his BG level needed to be lowered significantly. BG concentrations have been as follows:

Time	Glucose Concentration (mg/dL)
7 AM	60–320
Noon	140–280
5 PM	40–300

In the past year, G.O.'s A1C has decreased to 7.1%. Currently, he has approximately five hypoglycemic episodes per week, primarily in the late afternoon and early-morning hours. These are characterized by intense hunger, sweating, palpitations, and (according to his wife) a short temper. He has found that he can avoid nocturnal hypoglycemia (night sweats, nightmares, and headaches) by eating a large bedtime snack. During the past 3 months, he has gained 15 lb. Are G.O.'s signs and symptoms consistent with mild, moderate, or severe hypoglycemia? What are the causes?

G.O.'s case illustrates one of the major hazards of aggressive BG targets and intensive insulin therapy: hypoglycemia. Hypoglycemia is a fact of life for patients with Type 1 diabetes, virtually all of whom experience a hypoglycemic episode at one time or another. Nocturnal hypoglycemia is of particular concern. A syndrome called "dead-in-bed" has been described for patients with Type 1 diabetes, who experience repeated hypoglycemia and have an underlying cardiovascular pathology, and die in their sleep.[153]

Hypoglycemia is a BG concentration less than70mg/dL, and its occurrence is potentially fatal if not promptly recognized and treated. However, the exact level at which a patient experiences symptoms is difficult to define. Clinical hypoglycemia is associated with typical autonomic (neurogenic) and neuroglycopenic symptoms relieved by the administration of a quickly absorbed carbohydrate.

Pathophysiology

Normal brain function depends on glucose, the exclusive fuel for cerebral metabolism. Because the brain is unable to synthesize or store glucose, it must be provided with a constant exogenous quantity via the brain's blood supply. As BG concentrations fall, a series of physiologic responses occur to restore glucose levels. These responses create symptoms warning a patient to take corrective action by consuming carbohydrates. If these counter-regulatory responses fail to alert the patient and BG concentrations fall below a critical level, cognitive function becomes impaired, and confusion and coma may ensue.

In people without diabetes, the peripheral responses to hypoglycemia are so efficient that clinically important hypoglycemia probably never occurs. As glucose levels fall between 50 and 60 mg/dL, a series of neuroendocrine events occur, raising the plasma glucose concentration back toward normal by increasing hepatic glucose output. The major hormone responsible for producing acute recovery from insulin-induced hypoglycemia is glucagon; however, epinephrine alone also can produce near-normal recovery. Rising levels of adrenergic and cholinergic hormones generate warning symptoms of hypoglycemia. When hypoglycemia is prolonged, growth hormone and cortisone play a greater role in producing recovery.

Patients with Type 1 diabetes who maintain insulin depots throughout the day are predisposed to severe hypoglycemic reactions because deficiencies in the normal feedback system occur with time. Glucagon secretion becomes deficient within the first 2 to 5 years after diagnosis, and by 10 years or longer, epinephrine secretion may become impaired. The latter defect leads to asymptomatic hypoglycemia or hypoglycemic unawareness (see Case 53-9).

Certain circumstances predispose patients with Type 1 diabetes to severe hypoglycemia. These include (a) a defective counter-regulatory hormonal response to hypoglycemia (see Case 53-9), which may be further diminished with frequent hypoglycemia, (b) medications such as β-blockers that diminish early warning signs of impending hypoglycemia, (c) intensive insulin therapy that can alter secretion of counter-regulatory hormones, (d) skipped meals or inadequate carbohydrate intake relative to the insulin dose, (e) physical activity, and (e) excessive alcohol intake (Table 53-12).

Symptoms

The signs and symptoms associated with hypoglycemia vary in intensity according to the presence of cognitive deficits and the patient's ability to self-treat the reaction. They vary substantially from one patient to another. Symptoms are conventionally divided into two categories: neurogenic (or autonomic) and neuroglycopenic.[154]

Autonomic symptoms include sweating, intense hunger, palpitations, tremor, tingling, and anxiety. Epinephrine is thought to mediate many of the neurogenic responses to hypoglycemia.

Neuroglycopenic symptoms resulting from neuronal fuel deprivation (glucose) include difficulty concentrating, lethargy, confusion, agitation, weakness, and possibly, slurred speech, dizziness, and fainting. Profound behavioral changes, seizures, and coma are more severe manifestations of neuroglycopenia. Prolonged, severe neuroglycopenia ultimately results in death. Symptoms of mild, moderate, severe, and nocturnal hypoglycemia are as follows:

- Mild hypoglycemia: Symptoms include tremor, palpitations, sweating, and intense hunger. Diminished cerebral function is not present, and patients are capable of self-treating.
- Moderate hypoglycemia: Moderate hypoglycemic reactions include neuroglycopenic as well as autonomic symptoms: headache, mood changes, irritability, decreased attention, and drowsiness. Patients may require assistance in treating themselves because of the presence of impaired judgment or weakness. Symptoms are more severe, usually last longer, and often require a second dose of a simple carbohydrate.
- Severe hypoglycemia: Symptoms of severe hypoglycemia include unresponsivenes unconsciousness, or convulsions. These reactions require assistance from another individual for appropriate treatment. Approximately 10% of patients treated with insulin experience at least one severe, disabling episode of hypoglycemia per year that requires emergency treatment with parenteral glucagon or IV glucose.[154]
- Nocturnal hypoglycemia: Tingling of the lips and tongue is a common complaint o patients who experience nocturnal hypoglycemia. These patients also may complain of headache and difficulty arising in the morning, nightmares, or nocturnal diaphoresis.[154] Family members should be conscious of any unusual sounds or activity while the patient is sleeping.

G.O. has mild-to-moderate hypoglycemic reactions, which he is able to self-treat. These are likely caused by overinsulinization and insulin "stacking" (giving rapid- or short-acting insulin injections too close together, so that the doses "stack" on top of the other) with his rapid-acting insulin.

OVERINSULINIZATION

CASE 53-8, QUESTION 2: Evaluate G.O.'s overall control. What signs and symptoms in G.O. are consistent with overinsulinization and insulin stacking? How should he be managed?

The following is a list of signs and symptoms of overinsulinization in G.O.:

- A total daily insulin dose of more than 1 unit/kg. This dose is unusually high for a patient with Type 1 diabetes, who should not be resistant to the action of insulin.
- Weight gain in the past several months. This is secondary to the anabolic effects o

insulin as well as G.O.'s increased carbohydrate intake to match his high insulin doses for treatment of hypoglycemia.

- Frequent hypoglycemic reactions.
- High glycemic variability (i.e., BG concentrations that fluctuate wildly between hypoglycemia and hyperglycemia). In G.O.'s case, high BG concentrations may represent reactive hyperglycemia or overtreatment of hypoglycemic episodes. His low BG level may represent excessive rapid-acting insulin at bedtime and insulin stacking of his rapid-acting insulin after lunch. At lunchtime, he is administering a high-sugar correction dose of insulin glulisine too soon; his mealtime glulisine is still likely at a peak action and working to lower his prandial BG. By administering additional glulisine soon after the meal, the two insulin doses are adding up, or stacking, causing hypoglycemia.
- Near-normal A1C levels indicate mean BG concentrations that must be within the normal range even though the patient has recorded numerous high BG concentrations. Patients treated with intensive insulin therapy in the DCCT experienced hypoglycemic episodes 3 times more often than patients treated with standard insulin therapy.[29] A1C levels were approximately 7.2%.

G.O. should be managed by discontinuing his high-sugar corrections at bedtime and after lunch. He should check his BG premeal, 1 to 2 hours after meals, and at bedtime to obtain a better picture of his glucose patterns and insulin requirements. He should avoid the large bedtime snack because one should not have to add food just to avoid hypoglycemia (i.e., the insulin regimen should be adjusted). He should also begin testing his BG at 2 or 3 AM to

---

assess whether he is still experiencing nocturnal hypoglycemia after stopping the bedtime insulin glulisine. It will be important that he records the actual dose he administers before each meal and brings the record to clinic so that his insulin doses can be fine-tuned. Next, if he is capable, an algorithm for adjusting his preprandial insulin glulisine doses should be provided to minimize hypoglycemic and hyperglycemic reactions (see Case 53-2, Question 12), eventually he can transition to counting carbohydrates (see Case 53-2, Questions 11 and 12).

TREATMENT OF HYPOGLYCEMIA

CASE 53-8, QUESTION 3: How should G.O.'s hypoglycemic episodes be managed?

As G.O. illustrates, many patients with diabetes are frightened of hypoglycemia and have a tendency to over-treat their reactions with, for example, large quantities of juice or regular soda. This should be discouraged because overcorrection together with glucose generated by counter-regulatory hormones ultimately results in hyperglycemia.

The key to successful management of hypoglycemia is recognition and prevention. Because early warning symptoms of hypoglycemia vary from person to person, it is important that G.O. learns to recognize and pay attention to his earliest warning symptoms and treat early. Patients generally can recall prodromal symptoms after recovery from a severe hypoglycemic reaction if they have not developed hypoglycemic unawareness (see Case 53-9). As a caveat, occasionally patients "feel" hypoglycemic after their BG concentrations have been normalized from very high levels with intensive insulin therapy, owing to the amount of BG change. Encourage patients to test their BG level any time they "feel unusual" to verify a low BG concentration before treatment. G.O. should treat his symptoms only if he is truly hypoglycemic.

A second component of prevention is determining its cause and taking preventive or corrective action. This entails assessment of his diet (did he skip or delay a meal or change its content?), exercise pattern, time of insulin administration, insulin dose, and accuracy of carbohydrate counting and dose administered. If hypoglycemic reactions consistently occur at a certain time of day, he should determine whether this corresponds with a mealtime dose of his rapid-acting insulin and reduces that insulin dose by 1 to 2 units. If his FPG is running low, his insulin glargine dose can be reduced.

If a reaction occurs, G.O. should be instructed to treat it as follows (Table 53-12).

Mild Hypoglycemia

Most hypoglycemic reactions are managed readily with the equivalent of 10 to 20 g of glucose (see Table 53-12 for examples of carbohydrate sources containing 15 g of glucose). If the blood concentration remains low after 15 minutes, the patient should ingest another 10 to 20 g of carbohydrate. This quick-acting source of glucose should be followed by a small complex carbohydrate or protein snack (e.g., milk, peanut butter sandwich) to provide a continual source of glucose if a meal is not scheduled within the next 1 to 2 hours. An easy rule of thumb that can be used by patients is "15-15-15": 15 g of glucose followed by a second 15 g if the patient is still symptomatic after 15 minutes.

Glucose tablets are available and have the added benefit of being premeasured to prevent overtreatment of hypoglycemia. Glucose gels, liquid, or small tubes of cake frosting are useful for children or patients who become uncooperative and combative when hypoglycemic.

Moderate-to-Severe Hypoglycemia

Glucagon can be injected by the SC or IM (preferred) route into the deltoid or anterior thigh region. Glucagon is used when a patient is unable to self-treat their hypoglycemia caused by exogenous insulin. The dose of glucagon recommended to treat moderate or severe hypoglycemia for a child younger than 5 years of age is 0.25 to 0.5 mg; for children 5 to 10 years of age, 0.5 to 1 mg; and for patients older than

10 years, 1 mg. Parents, spouses, or other close contacts should be taught how to mix, draw up, and administer glucagon during emergency situations. Kits with prefilled syringes containing 1 mg glucagon are available. Patients who are given glucagon should be positioned so that their face is turned toward the floor to prevent aspiration in the event of vomiting. As soon as the patient awakens (10–25 minutes), he/she should be fed.

Intravenous Glucose

If glucagon is unavailable, the patient should be taken to the hospital's emergency department, where he/she can be treated with IV glucose (~10–25 g administered as 20–50 mL of 50% dextrose for 1–3 minutes) in preference to glucagon. After the bolus injection of glucose, IV glucose (5–10 g/hour) should be continued until the patient has gained consciousness and is able to eat.

HYPOGLYCEMIC UNAWARENESS

CASE 53-9

QUESTION 1: M.M., a 35-year-old, 75-kg, unemployed man, has had Type 1 diabetes since the age of 3. As a consequence of the diabetes, he has developed proliferative retinopathy and progressive diabetic nephropathy (current SCr, 2.2 mg/dL). M.M. has an erratic lifestyle. Because he does not work, he often stays out late at night and sleeps late into the morning. His insulin is injected whenever he awakens, and his meals are irregularly spaced. Each time he comes to the clinic, he brings with him a complete log of glucose concentrations that range from 80 to 140 mg/dL. He has two to three severe hypoglycemic reactions a month that require trips to the emergency department for treatment with IV glucose. On several occasions, his BG concentration has been 30 mg/dL, and he states he may feel a little weak, but otherwise feels "not too bad." M.M.'s last A1C was 10%. He says that he adheres to the following insulin regimen: 18 units NPH/11 units regular insulin before breakfast, 10 units regular insulin before lunch and dinner, and 14 units NPH at bedtime.

At this visit, M.M. comes with his girlfriend. He has a large gash on his nose that occurred 3 days ago when he lost consciousness at approximately 1:30 PM while pushing his stalled car. He was unable to eat lunch at the usual hour because he had problems with his car. Assess M.M.'s hypoglycemic reactions and BG control. Should his current insulin regimen be continued? How should he be managed?

M.M. illustrates a patient with Type 1 diabetes who has defective glucose counter-regulation and, as a result, is unable to counteract a hypoglycemic reaction effectively. He also is an example of a patient who should not have aggressive BG targets because he does not feel the symptoms of a low blood sugar and has already developed end-stage organ damage (proliferative retinopathy and nephropathy). Neither is likely to be reversed with improved glycemic control. In fact, proliferative retinopathy may actually worsen with intensive insulin therapy initially.[38] In the DCCT study, severe hypoglycemic reactions were 3 times more common among patients treated with intensive insulin therapy, and nocturnal hypoglycemia accounted for 41% of the total hypoglycemic episodes.[29] In patients with defective counter-regulation, the risk of severe hypoglycemia may be 25 times higher than in patients with adequate counter-regulatory mechanisms treated with intensive insulin therapy.[154] M.M. is at great risk for death secondary to hypoglycemia.

M.M.'s lifestyle is erratic, he eats irregularly, and his reported BG concentrations (80–140 mg/dL) do not correspond to his elevated A1C value. This may indicate that M.M.'s technique is incorrect or that he simply fills in the log with fictitious numbers before he comes to the clinic. Irregular entries in different colored inks and bloodstains usually indicate authentic records.

As noted, the primary hormones that are secreted in response to a low BG concentration are glucagon and epinephrine. In patients who have had Type 1 diabetes for longer than 2 to 5 years, a deficiency in glucagon secretion is a relatively consistent finding, and these patients must rely on epinephrine to reverse low BG concentrations.[155] Unfortunately, approximately 40% of patients with long-standing Type 1 diabetes (8–15 years) have defective epinephrine secretion as well, and this may be related to the development of autonomic neuropathy. Patients whose diabetes is tightly controlled also have reduced counter-regulatory hormone responses to hypoglycemia. As illustrated by M.M., patients with defective epinephrine secretory responses also lose the warning signs and symptoms of hypoglycemia. These patients are said to have hypoglycemia unawareness because they have no awareness of BG concentrations less than 50 mg/dL. In these individuals, loss of consciousness, seizures, or irrational behavior may be the first objective sign of exceedingly low BG concentrations. The glycemic threshold for symptoms also is lowered in patients on intensive insulin therapy whose glucose concentrations have been lowered to normal or near-normal levels.[154] Consequently, their hypoglycemic reactions may go unnoticed and untreated until they lose consciousness. M.M. should be managed as follows:

- Because his waking, sleeping, and eating patterns are highly irregular, M.M. shoul be treated with an insulin regimen that addresses his lifestyle. For example, he could be switched to a basal-bolus insulin regimen, in which he can give himself a rapid-acting insulin just before he actually intends to eat. A dose of insulin glargine or detemir could be given before his first meal to supply a basal level of insulin between meals. Additionally, when switching to insulin glargine or detemir MM should be provided this insulin in a pen formulation as to avoid any dosing errors from drawing insulin into a syringe based on MM's current symptoms of visual impairment.
- Because M.M. has no warning symptoms for hypoglycemia, the importance of regular SMBG should be emphasized. When BG testing was reviewed with M.M., it was discovered that his eyesight was so poor that he was unable to distinguish between the right and wrong side of the glucose test strip. Furthermore, because he had lost his depth of field, he was unable to apply the

drop of blood into the test strip. To address this situation, M.M.'s girlfriend was taught how to perform BG testing. Also, a glucose monitor that requires a very small blood sample and beeps with an adequate blood sample would be beneficial for him.

- M.M.'s girlfriend also was taught how to recognize and treat symptoms of hypoglycemia and how to administer glucagon. Often, patients ignore early warning symptoms and progress to a point that they lose the judgment needed to treat the condition. If M.M. has not yet become combative, a quick-acting carbohydrate source should be offered. If he has lost consciousness, glucagon should be injected.

All of these maneuvers diminished the frequency of M.M.'s severe hypoglycemic reactions. On the whole, his BG concentrations were maintained below 180 mg/dL, and he remained relatively free of hyperglycemic symptoms. M.M.'s A1C using a basal-bolus insulin regimen was 8.0%.

DIABETIC KETOACIDOSIS

CASE 53-10

QUESTION 1: J.L., a 40-year-old, 60-kg woman with an 8-year history of Type 1 diabetes, is moderately well controlled on 24 units of insulin glargine plus premeal doses of insulin lispro. Her family brings her to the emergency department, where she complains of abdominal tenderness, nausea, and vomiting. According to her family, J.L. was well until 2 days ago when she awoke with nausea, vomiting, diarrhea, and chills. Because she has been unable to eat, she has omitted her usual morning dose of insulin for the past 2 days. Her gastrointestinal (GI) symptoms progressed, and she was brought to the emergency department when she became lethargic.

Physical examination reveals an ill-appearing woman who is lethargic but responsive. Her temperature is 37°C. Skin turgor is poor, mucous membranes are dry, and her eyeballs are shrunken and soft. J.L.'s lungs are clear, but respirations are deep and her breath has a fruity odor. Cardiac examination is within normal limits.

In the supine position, J.L.'s pulse rate is 115 beats/minute and her BP is 105/60 mm Hg. In the upright position, her pulse increased to 140 beats/minute, and her BP dropped to 85/40 mm Hg. There is mild, diffuse tenderness over her abdomen.

Laboratory results on admission disclosed the following:

BG, 450 mg/dL
Sodium (Na), 150 mEq/L
Potassium (K), 5.4 mEq/L
Chloride (Cl), 106 mEq/L
HCO_3, 10 mEq/L
SCr, 2.0 mg/dL
Hemoglobin, 15.7 g/dL
Hematocrit, 49%
White blood cell count, 15,000/µL with 3% bands (normal, 3%–5%), 70% polymorphonuclear neutrophils (normal, 54%–62%), and 27% lymphocytes (normal, 25%–33%)
Serum ketones, moderate at 1:10 dilution (normal, negative)

The urinalysis showed the following:

Glucose, 2+ (normal, 0)
Moderate ketones (normal, 0)
pH, 5.5 (normal, 4.6–8)
Specific gravity, 1.029 (normal, 1.020–1.025)
No white blood cells, red blood cells, bacteria, or casts
Arterial blood gas results were as follows:
pH, 7.05 (normal, 7.36–7.44)
Pco_2, 20 mm Hg (normal, 35–45)
Po_2, 120 mm Hg (normal, 90–100)

What supports the diagnosis of DKA in J.L.?

The fact that J.L. has Type 1 diabetes puts her at risk for developing ketoacidosis. About 80% of DKA cases occur in patients older than 18 years of age with about one-third of those occurring in patients older than 45 years of age.[151] In DKA, an absolute or relative insulin deficiency promotes lipolysis and metabolism of free fatty acids to β-hydroxybutyrate, acetoacetic acid, and acetone in the liver. Excess glucagon enhances gluconeogenesis and impairs peripheral ketone utilization. Physiologic stress contributes to the development of DKA by stimulating release of insulin counter-regulatory hormones including glucagon, catecholamines, glucocorticoids, and growth hormone. Common stress factors include infection, pregnancy, pancreatitis, trauma, hyperthyroidism, and acute MI.

J.L. presented with symptoms of nausea, vomiting, diarrhea, and chills, and these are suggestive of an acute viral gastroenteritis.

Patients such as J.L. commonly discontinue their insulin in this setting, which can rapidly precipitate the development of DKA (see Case 53-5) . Table 53-22 lists patient education points with regard to DKA.

As illustrated by J.L., patients with DKA present with moderate-to-high serum glucose concentrations secondary to decreased peripheral utilization and increased hepatic production (Table 53-23). This increases serum osmolality, which initially shifts fluid from the intracellular to the extracellular space. When serum glucose concentrations exceed the renal threshold for reabsorption of about 200 mg/dL, glucose “spills” over into the urine and causes an osmotic diuresis that depletes the total body water and electrolytes. J.L. also has lost fluid and electrolytes from vomiting and diarrhea. Eventually, as losses exceed input, the patient becomes dehydrated (dry mucous membranes; dry skin; soft, shrunken eyeballs; increased hematocrit), and intravascular volume becomes depleted (orthostatic BP and pulse changes).

The finding of hyperkalemia in J.L. is also common in DKA because insulin contributes to the intracellular shift of potassium.[156] The relative deficiency of insulin in DKA results in an extracellular shift of potassium that is worsened by the acidosis that often develops.[157] A finding of hypokalemia in DKA (<3.3 mg/dL) is uncommon and is a marker of more severe disease. In the hypokalemic patient, the combination of the extracellular shift of potassium and polyuria has led to excessive depletion of total body potassium. Care must be used in these patients to replace potassium intravenously before beginning insulin therapy, which will cause further hypokalemia as potassium shifts back into cells.[156]

Table 53-22

Diabetic Ketoacidosis: Patient Education

Definition: DKA occurs when the body has insufficient insulin

Questions to Ask

1. Has insulin use been discontinued or a dose skipped for any reason?
2. If an insulin pump is being used, is the tubing clogged or twisted? Has the catheter become dislodged?
3. Has the insulin being used lost its activity? Is the bottle of rapid-acting/regular or basal insulin cloudy? Does the bottle of NPH look frosty?
4. Have insulin requirements increased owing to illness or other forms of stress (infection, pregnancy, pancreatitis, trauma, hyperthyroidism, or MI)?

What to Look For

1. Signs and symptoms of hyperglycemia: thirst, excessive urination, fatigue, blurred vision, consistently elevated blood glucose concentrations (>300 mg/dL)
2. Signs of acidosis: fruity breath odor, deep and difficult breathing
3. Signs of dehydration: dry mouth; warm, dry skin; fatigue
4. Others: stomach pain, nausea, vomiting, loss of appetite

What to Do

1. Review "sick day management" (Table 53-20)
2. Test blood glucose ≥4 times daily
3. Test urine for ketones when blood glucose concentration is >300 mg/dL
4. Drink plenty of fluids (water, clear soups)
5. Continue taking insulin dose
6. Contact physician immediately

DKA, diabetic ketoacidosis; MI, myocardial infarction; NPH, neutral protamine Hagedorn.

Table 53-23

Common Laboratory Abnormalities in Diabetic Ketoacidosis (DKA)

Glucose	250 mg/dL
Serum osmolarity	Variable, can be >320 mOsm/kg in presence of coma
Sodium	Low, normal, or high[a]
Potassium	Normal or high
Ketones	Present in urine and blood
pH	Mild: 7.25–7.30
	Moderate: 7.00–7.24
	Severe: <7.00

Bicarbonate	Mild: 15–18 mEq/L
	Moderate: 10 to <15 mEq/L
	Severe: <10 mEq/L
WBC count	15,000–40,000 cells/µL even without evidence of infection

[a] Total body sodium is always low.
WBC, white blood cell.

Evidence of excessive ketone production in J.L. includes ketonuria, ketonemia, and the characteristic fruity odor of acetone on the breath. Elevated levels of these organic acids increase the anion gap and decrease the pH and carbonate levels. The respiratory rate is increased to compensate for the metabolic acidosis leading to hypercapnia.[156,158]

Treatment

CASE 53-10, QUESTION 2: How should J.L. be treated?

Treatment of patients with DKA is aimed at expansion of intravascular and extravascular volume, replacement of electrolyte losses, and cessation of ketone production (Table 53-24).

FLUIDS

Rapid correction of fluid loss is most crucial. The usual fluid deficit is difficult to estimate in the absence of overt hypernatremia but approximates 5% to 10% of body weight in most patients depending on the severity of the DKA. In the absence of cardiac compromise, hypernatremia, or significant renal dysfunction, isotonic saline (0.9% NaCl) should be used.[151]

J.L. has evidence of significant dehydration and intravascular volume depletion. Based on body weight, if the patient has the typical 5% to 10% weight loss, that would indicate approximately 3 to 6 L of fluid will be needed to fully replete (10% of 60 kg = 6-kg loss and 1 L = 1 kg). It is recommended that fluids be replaced at the rate of 15 to 20 mL/kg/hour during the first hour (~1 to 1.5 L in the average adult). The subsequent choice for fluid replacement depends on the patient's state of hydration, serum electrolyte levels, and urinary output. If the corrected sodium is normal or elevated, 0.45% NaCl infused at a rate of 4 to 14 mL/kg/hour is appropriate. If the corrected serum sodium is low, 0.9% NaCl is preferred.[156] When serum glucose concentrations approach 200 mg/dL, solutions should be changed to D5W/0.45% NaCl. Glucose is added to allow the continuation of insulin therapy without causing hypoglycemia (see Case 53-10, Question 5).[156]

Table 53-24

Management of Diabetic Ketoacidosis[156]

Fluid Administration
Start IV fluids using normal saline (0.9% NaCl) unless patient has cardiac compromise
Rate is 15–20 mL/kg body weight or 1–1.5 L during first hour
Then, if corrected sodium is normal or elevated, use 0.45% NaCl at a rate of 4–14 mL/kg/h (250–500 mL/hour). Use 0.9% NaCl if corrected sodium is low
Once serum glucose reaches 200 mg/dL, change to 5% dextrose with 0.45% NaCl at 150–250 mL/hour
Insulin
Continuous IV infusion of regular insulin is preferred. Use IM route only if infusion is not available
Bolus dose: 0.1 units/kg IV
Maintenance dose: 0.1 units/kg/h IV
If blood glucose level has not decreased by 50–75 mg/dL after 1 hour, double infusion rate
Once blood glucose reaches 200 mg/dL, reduce infusion rate to 0.05–0.1 units/kg/hour and change fluid to 5% dextrose with 0.45% NaCl (do not stop insulin infusion)
When SC insulin can be initiated, administer dose 1–2 hours before discontinuing IV infusion
For uncomplicated DKA, SC rapid-acting insulin can be considered. A bolus dose of 0.2 units/kg followed by 0.1 units/kg every hour or an initial dose of 0.3 units/kg followed by 0.2 units/kg every 2 hours until the blood glucose reaches <250 mg/dL; then the SC insulin dose is decreased by half (to either 0.05 or 0.1 units/kg every 1–2 hours)
Potassium
Establish adequate renal function (urine output ~50 mL/hour). If K is <3.3 mEq/L, hold insulin and give 20–40 mEq/hour until K >3.3 mEq/L. If K is >5.5mEq/L, do not give K and check serum K every 2 hours. If K is >3.3 but <5.3 mEq/L, give 20–30 mEq in each liter of IV fluid to maintain K between 4 and 5 mEq/L
Phosphate
Initiate if level <1 mg/dL, or in patients with cardiac dysfunction, anemia, or respiratory depression. Use potassium phosphate salt, 20–30 mEq added to replacement fluid. Rarely needed
Bicarbonate
Replacement is controversial and may be dangerous
For adults with pH <6.9, 100 mmol of sodium bicarbonate may be added to 400 mL of sterile water with 20 mEq of KCl; infuse for 2 hours (200 mL/hour). For adults with pH of 6. 9–7.0, 50 mmol of sodium bicarbonate diluted in 200 mL of sterile water with 10 mEq of KCL; infuse for 1 hour (200 mL/hour). No bicarbonate is necessary if pH >7.0

DKA, diabetic ketoacidosis; IM, intramuscular; IV, intravenous; SC, subcutaneous.

SODIUM

Total body sodium usually is depleted by 7 to 10 mEq/kg of body weight in patients with DKA. In assessing serum sodium in these patients, it is important to remember that falsely low values (i.e., pseudohyponatremia) may be the result of hyperglycemia and hypertriglyceridemia. A corrected sodium value can be estimated by adding 1.6 mEq/L to the observed sodium value for every 100 mg/dL glucose in excess of 100 mg/dL. Sodium is replaced adequately with normal saline, which has a sodium concentration of 154 mEq/L.[156]

POTASSIUM

Potassium balance is altered markedly in patients with DKA because of combined urinary and GI losses. Invariably, total body potassium is at least partly depleted; however, the serum potassium concentration may be high, normal, or low, depending on the degree of acidosis and volume contraction and severity of insulin deficiency. Usual potassium deficits in this situation average 3 to 5 mEq/kg of body weight, although they may be as high as 10 mEq/kg.[156,158]

Thus, J.L. needs approximately 200 to 350 mEq of potassium to replenish her body stores, assuming her normal weight is 70 kg. To prevent hypokalemia, potassium replacement should be started after her serum potassium concentrations decrease to less than 5.3 mEq/L (assuming an adequate urine output of 50 mL/hour). The addition of 20 to 30 mEq/L is usually sufficient to maintain the serum potassium at greater than 4 mEq/L. In cases when serum potassium is low at presentation (<3.3 mEq/L), potassium replacement should be initiated with fluid therapy, and insulin therapy delayed until the potassium level is greater than 3.3 mEq/L to avoid severe hypokalemia and the risk of cardiac arrhythmias and diaphragmatic weakness. In these cases, initial IV solutions should contain 20 to 30 mEq/L of potassium chloride.

PHOSPHATE

Phosphate is lost as the result of increased tissue catabolism, impaired cellular uptake, and enhanced renal excretion. Like other electrolytes, serum levels initially may seem normal, even though body stores are depleted. However, replacement can result in hypocalcemia, and the use of phosphate in DKA has resulted in no clinical benefit to patients.[156] Severe hypophosphatemia (<1.0 mg/dL) can cause cardiac and skeletal muscle weakness as well as respiratory depression. To avoid this, phosphate can be carefully replaced in patients with cardiac dysfunction or respiratory depression when phosphate concentrations are less than 1.0 mg/dL. Potassium phosphate can be added to the replacement fluids in the amount of 20 to 30 mEq/L.

INSULIN

CASE 53-10, QUESTION 3: What is an appropriate insulin dose and route of administration for J.L.?

Insulin therapy is the key to DKA management because it is what stops the production of ketones. As insulin allows glucose metabolism to resume, the counter-regulatory signals for ketone production are turned off. Unless the episode of DKA is mild (pH 7.25–7.30) and uncomplicated, regular insulin by continuous infusion is the treatment of choice. Once hypokalemia (K^+ <3.3 mEq/L) is excluded or treated, an IV bolus of regular insulin at 0.1 units/kg followed by a continuous infusion at a dose of 0.1 units/kg/hour should be administered. This should decrease the plasma glucose by at least 10% in the first hour. If there is not at least a 10% reduction in the first hour, then a second bolus of 0.15 units/kg should be administered. Once the plasma glucose reaches 200 mg/dL, the insulin infusion can be decreased to 0.05 units/kg/hour. Alternatively, insulin can be switched to SC at a dose of 0.1 units/kg every 2 hours. Regardless of the route of insulin therapy, serum glucose should be maintained at less than 200 mg/dL.[156] At this point, the fluid should be changed to D5W with 0.45% NaCl. Thereafter, the rate of insulin administration and the rate of infusion of D5W with 0.45% NaCl are adjusted to maintain the glucose value at around 200 mg/dL until the ketosis is resolved.[156] Resolution of ketosis is marked by a serum bicarbonate level of at least 15 mEq/L, a venous pH greater than 7.3, and a calculated anion gap of 12 mEq/L or less. Once any two of those three findings are present, the patient can be converted to a longer-acting SC regimen.

For mild DKA (serum bicarbonate ≥15 mEq/L, anion gap <15), SC rapid-acting insulin has been used with no differences in patient outcomes. The advantage is that patients can be treated in a non-ICU setting, thus reducing hospital costs. The dosing for rapid-acting insulin is included in Table 53-24.

SODIUM BICARBONATE

CASE 53-10, QUESTION 4: J.L. was treated with fluids, electrolytes, and insulin as discussed in previous questions. Laboratory and clinical data 4 hours after therapy are as follows:

pH, 7.1
BG, 400 mg/dL
K, 3.8 mEq/L
SCr, 3.1 mg/dL
Serum ketones, strongly positive at a 1:40 dilution

Her BP was 120/70 mm Hg with no orthostatic changes. Urine output for the past 3 hours has been 500 mL. Because serum ketones have increased, should J.L. receive more insulin? Should she receive bicarbonate therapy?

The assumption that ketosis is worse in J.L. is incorrect. In DKA, low levels of insulin and elevated glucagon levels promote the metabolism of free fatty acids in the liver to acetoacetate and β-hydroxybutyrate. The standard nitroprusside reaction test for ketones measures only acetoacetate, even though β-hydroxybutyrate is the more important ketone. The conversion of acetoacetic acid to β-hydroxybutyrate is coupled closely with the reduced NADH:NAD ratio. If this ratio is high (as in the presence of alcohol), so much β-hydroxybutyrate may be formed that acetoacetate is virtually undetectable; thus, the absence of ketones in the serum does not rule out ketoacidosis.

Conversely, treatment with insulin begins to suppress lipolysis and fatty acid oxidation; nicotinamide adenine dinucleotide is regenerated, shifting the reaction back in favor of acetoacetate.[156] Thus, even though there seem to be higher concentrations of ketones in the serum, J.L.'s declining BG concentration, improved bicarbonate concentrations, and improved acid–base and cardiovascular responses indicate that she is responding appropriately. Therefore, no change in the insulin dose is indicated. It is important to emphasize that the glucose concentrations normalize before ketones (4–6 hours vs. 6–12 hours) because the latter are metabolized more slowly. For this reason, it is important to continue insulin to maintain suppression of lipolysis until plasma and urine ketones have cleared.

The use of bicarbonate in patients with DKA has been controversial.[151] Most investigators discourage its routine use, reserving it for patients with severe acidemia (pH <6.9) or those in clinical shock. Coma is correlated most closely with BG concentrations (>700 mg/dL) and hyperosmolality (calculated osmolality >340 mOsm/kg).[156] In a small randomized, prospective study, bicarbonate did not affect recovery in patients with severe DKA (arterial pH, 6.9–7.14).[159] Thus, even though J.L.'s acidosis seemed severe on admission (pH, 7.05; bicarbonate, 10 mEq/L; Kussmaul respirations [deep, frequent respirations resulting in blowing off of CO_2]), bicarbonate was not administered. It is apparent that with fluid and insulin therapy alone, her acidosis is beginning to improve.

CASE 53-10, QUESTION 5: What is the expected course of DKA in J.L.?

After 3 L of fluid and a constant insulin infusion of 6 units/hour for 3 hours, J.L.'s glucose concentration had dropped to 400 mg/dL and she had no orthostatic BP changes, reflecting recovery from her volume-depleted status. Potassium (40 mEq/L) was added to her fluids, which were administered at a reduced rate of 300 mL/hour.

Three hours later, the glucose concentration had dropped to 350 mg/dL and her pH had increased to 7.21 with an anion gap of 24 mEq/L. The serum potassium remained low-normal at 3.4 mEq/L, and serum sodium increased to 151 mEq/L. In view of these changes, the IV infusion fluid was changed to half-normal saline with 5% dextrose to which 40 mEq/L of potassium was added. The rate was slowed to 250 mL/hour, and the insulin infusion was continued at 6 units/hour.

Four hours later (10 hours after admission), the BG was 205 mg/dL and the serum potassium was 3.5 mEq/dL. The IV fluids were changed to 5% dextrose with 40 mEq/L of potassium chloride, administered at a rate of 250 mL/hour, and the regular insulin infusion was decreased from 6 to 3 units/hour. J.L. continued to improve during the next 12 hours, and she began taking full oral liquids by the second hospital day. At that time, her IV infusion rate was decreased to 200 mL/hour, but her insulin infusion was continued.

Approximately 24 hours after admission, J.L.'s BG concentration was 175 mg/dL, potassium was 4.6 mEq/L, sodium was 144 mEq/L, and the anion gap had closed down to 16 mEq/L. There were no ketones in the plasma. The urine contained 1% glucose and moderate amounts of ketones. IV fluids were discontinued, and a rapid-acting insulin was administered SC 1 hour before the insulin infusion was discontinued. J.L. continued to receive rapid-acting insulin SC every 4 hours according to a sliding scale (see Case 53-2, Question 12). Thirty-six hours after admission, J.L. was given her usual dose of insulin glargine and insulin lispro and was sent home for follow-up in the clinic.

TREATMENT OF TYPE 2 DIABETES: ANTIDIABETIC AGENTS

Type 2 diabetes must be managed in the context of the metabolic syndrome. At the time of diagnosis, many people with Type 2 diabetes already have evidence of macrovascular and microvascular

disease. Every effort to lower glucose concentrations toward normal values and to control BP and lipids is important to delay the onset or slow the progression of these complications, improve the overall quality of the patient's life, and save the healthcare system millions of dollars in hospitalization costs to treat these complications. MNT, physical activity, and SMBG are cornerstones in the treatment of people with Type 2 diabetes. Unfortunately, these measures alone are usually not successful in achieving control for the majority of patients, and drug therapy is eventually required. Because these patients also often require a number of medications to treat related conditions (e.g., hypertension, dyslipidemia, CVD, and depression) and may also be medicating themselves with over-the-counter drugs, herbal products, and nutritional supplements, the aim of therapy for Type 2 diabetes should be the simplest and safest regimen that provides the best glycemic control possible.

Tables 53-25 and 53-26 summarize the comparative pharmacology, pharmacokinetics, and dosing of the noninsulin antidiabetic drugs. The clinical use of these agents in specific situations is illustrated in cases presented later in this chapter.

Biguanides

Metformin belongs to the biguanide class of oral antidiabetic agents. It has been available in the United States since 1995 and became generically available in 2002. Currently, both the immediate-release and the extended-release formulations are available generically. The clinical pharmacology of metformin has been extensively reviewed.[160]

MECHANISM OF ACTION

The biguanides are described more accurately as antihyperglycemic agents. Although they lower BG concentrations in people with Type 2 diabetes, they do not cause hypoglycemia in nondiabetic individuals or individuals with diabetes when used as monotherapy. Partly because of this lack of hypoglycemia, metformin is recommended by the ADA to reduce the risk for developing diabetes in patients at high risk (IGT and IFG) because of its strong evidence base and long-term safety. Metformin is considered first-line therapy for diabetes because it is the only agent with outcome data showing a reduction in all-cause mortality and vascular complications independent of glycemic control.[7,160] Metformin primarily lowers FPG concentrations by decreasing hepatic gluconeogenesis, but it also increases insulin-stimulated glucose uptake by skeletal muscle and adipose tissue and also decreases intestinal absorption of glucose.[160]

Metformin has been shown to activate 5′ adenosine monophosphate-activated protein kinase (AMPK), a major regulator of glucose and lipid metabolism.[161] The primary cellular site of metformin is thought to be complex I in the mitochondria, whose inhibition by metformin leads to the activation of AMPK.[162] Through AMPK activation, acetyl-CoA carboxylase is inactivated, resulting in decreased lipid synthesis and increased fatty acid oxidation. Sterol regulatory element-binding protein-1, a key lipogenic transcription factor, is also suppressed, leading to a reduction in hepatic lipid production. AMPK activation is also thought to play a role in metformin's inhibition of hepatocyte glucose production and induction of muscle glucose uptake.[161,163]

Metformin modestly lowers total cholesterol and triglycerides and may maintain or improve HDL-C levels.[164] The observed effects on lipid metabolism as well as others on clotting factors, platelet function, and vascular function may impart some of metformin's favorable effects on CVD and outcomes (see Case 53-11, Question 3). A key advantage with metformin is that weight loss rather than weight gain is more likely to occur with its use (mean weight loss of 0.5 to 3.8 kg can occur in adults receiving metformin immediate-release tablets as monotherapy and negligible weight loss occurs with extended-release tablets).[164]

PHARMACOKINETICS

Approximately 50% to 60% of metformin is absorbed from the small intestine, and peak plasma concentrations are achieved at approximately 2.5 hours.[164] Approximately 10% of an oral dose is excreted in the feces and about 90% of a dose is excreted through an active tubular process in the kidneys. The rate and extent of absorption are both decreased by food. Metformin has a plasma half-life of 6.2 hours in patients with normal renal function and a whole-blood half-life of 17.6 hours.[164] It is not bound to plasma proteins.

ADVERSE EFFECTS

Gastrointestinal Effects

Transient side effects include diarrhea and other GI disturbances such as nausea, abdominal discomfort, metallic taste, flatulence and anorexia.[164] Relative to placebo, diarrhea is the most common GI complaint with immediate-release tablets (53.2% metformin vs. 11.7% placebo-treated patients) and occurs in roughly 9.6% of patients taking extended-release tablets. Symptoms can be minimized by taking metformin with food and slowly titrating the dose. To enhance adherence to therapy, patients should be informed of the possibility of GI side effects that will likely subside with continued use, and instructed to discuss any suspected side effects with their provider before discontinuing therapy (see Case 53-11, Question 4).

Lactic Acidosis

Much of the perceived risk of lactic acidosis secondary to metformin use is based on historical data for phenformin, a biguanide that was withdrawn from the market in 1977.[165] The risk of lactic acidosis secondary to metformin is 10 to 20 times lower than with phenformin. Unlike phenformin, metformin is not metabolized, does not inhibit peripheral glucose oxidation, and does not enhance peripheral lactate production.[166] However, it may decrease conversion of lactate to glucose (decreased gluconeogenesis) and increase lactate production in the gut and liver.[166,167] Metformin has rarely been associated with lactic acidosis. The few patients in whom this event has been reported had renal, liver, or cardiorespiratory contraindications to the use of biguanides. A Cochrane review including 347 studies compared the risk of lactic acidosis among patients taking metformin, placebo, or other nonbiguanide therapies. The review found no difference between groups in either lactate levels or in the development of lactic acidosis.[157] Despite the rarity of lactic acidosis with metformin therapy, patients should be warned to bring the following symptoms of lactic acidosis to the attention of their physician: weakness, malaise, myalgias, abdominal distress, and heavy, labored breathing (see Case 53-16, Question 2).

CONTRAINDICATIONS AND PRECAUTIONS

Patients with renal impairment, liver disease, or other states predisposing them to hypoxia, acute or chronic metabolic acidosis, DKA, or a history of lactic acidosis should be excluded from therapy.[164] Metformin can accumulate in patients whose renal function is impaired, thereby increasing their risk for lactic acidosis. For this reason, metformin caries a black box warning. Its use is not recommended in patients with a decreased GFR (see Dosage and Clinical Use; see Case 53-16, Question 2, for detailed discussion) or elevated creatinine levels (≥1.4 mg/dL for women or ≥1.5 mg/dL for men[164]). Because even a temporary reduction in renal function could cause lactic acidosis in patients taking metformin, the manufacturer recommends withholding it after some radiologic procedures (see Drug Interactions section).

Other predisposing factors for lactic acidosis include the following: excessive alcohol ingestion, dehydration, surgery, decompensated congestive HF, hepatic failure, shock, or sepsis. Because aging is associated with reduced renal function, metformin should be titrated to the minimal effective dose and renal function should be monitored regularly. An estimated GFR (eGFR) or creatinine clearance (ClCr) should be measured in patients older than 80 years of age to ensure adequate renal function prior to metformin use, because these patients are more susceptible to experiencing lactic acidosis.[164]

DRUG INTERACTIONS

- Alcohol potentiates the effect of metformin on lactate metabolism. Patients should be warned against excessive alcohol intake while taking metformin. Metformin should be avoided in patients who are alcoholics.
- Vitamin B_{12} absorption may be decreased in patients taking metformin. Each 1 g/d increment dose of metformin significantly increases the odds of vitamin B_{12} deficiency, as well as taking metformin therapy for more than 3 years.
- Dofetilide should not be administered in patients taking metformin due to the competition for common renal tubular transport systems, which may result in an increase in the plasma concentrations of either drug.
- Topiramate should be avoided in patients on metformin because topiramate may increase the risk of developing lactic acidosis.
- Parenteral contrast studies (e.g., pyelography or angiography) that use iodinated materials can result in acute renal failure and increase the risk of metformin-induced lactic acidosis. For patients requiring such a study, metformin should be withheld at the time of or before and for 48 hours after the procedure. Metformin should be reinstituted only after renal function has been re-evaluated and determined to be normal.

EFFICACY

As monotherapy, metformin can be expected to reduce the A1C by 1.3% to 2.0% and the FPG by 50 to 70 mg/dL.[160] Research suggests that certain genetic variations may impact patient response to metformin therapy. Patients exhibiting reduced function polymorphisms of organic cation transporter 1, which is involved in the hepatic uptake of metformin, may be less responsive to metformin therapy.[168]

DOSAGE AND CLINICAL USE

Metformin is the first line of therapy for Type 2 diabetes.[7,38] The ADA recommends its initiation as monotherapy in combination with lifestyle interventions (e.g., MNT, physical activity, weight-loss education, lifestyle education) on diagnosis. To minimize GI side effects, metformin should be initiated at 500 mg twice a day or 850 mg once a day, to be taken with food, followed by weekly increases in 500 mg increments or 850mg increases every 2 weeks (see Case 53-11, Question 4).

Metformin is dosed 2 to 3 times daily (500–1,000 mg/dose; maximal dose 2,550 mg/day or 850 mg PO 3 times a day [TID]), unless an extended-release preparation is prescribed. Using the ER formulation as initial therapy may decrease GI side effects. It should still be initiated at 500 mg daily and titrated similarly. It can, however, be dosed once a day, usually with the evening meal. Clinicians should obtain a SCr/eGFR (using the Modification of Diet in Renal Disease equation) and hepatic function tests at baseline and then annually. A recent review[169] recommends that metformin dose reduction should be considered in patients with an eGFR <45 mL/minute/1.73 m^2 and the TDD should not exceed 1,000 mg/day. Renal function should be closely monitored in these patients every 3 months. Metformin should be discontinued in patients with an eGFR <30 mL/minute/1.73 m^2 or in patients with additional risk factors such as hypotension, hypoxia, sepsis, or an increased risk for acute kidney injury (e.g., use of radiocontrast dye in patients with an eGFR <60 mL/minute/1.73 m^2). Metformin should not be used in patients older than 80 years unless a ClCr/eGFR demonstrates normal renal function.[7] Patients are good candidates for treatment if the ClCr is more than 60 mL/minute (or eGFR >60 mL/minute/1.73 m^2). For patients unable to achieve goals of therapy with metformin alone within 3 months of initiating therapy, addition of insulin or another agent should be considered (also see Case 53-13).

Nonsulfonylurea Insulin Secretagogues (Glinides)

Repaglinide (Prandin) and nateglinide (Starlix) are nonsulfonylurea insulin secretagogues (i.e., they stimulate insulin secretion). They belong to a class of agents referred to as meglitinides and are often called “glinides.” Repaglinide was approved by the FDA in December 1997, and nateglinide was approved in December 2000 (Table 53-25).

MECHANISM OF ACTION

These agents close the adenosine triphosphate (ATP)-sensitive potassium channels in the β-cell, which leads to cell membrane depolarization, an influx of calcium, and secretion of insulin. The release of insulin depends on the glucose level and decreases at low concentrations of glucose.[170,171] Unlike the sulfonylureas, they have a rapid onset and shorter duration of action, so they are given with meals to enhance postprandial glucose utilization.

PHARMACOKINETICS

Repaglinide has a bioavailability of 56% and is rapidly absorbed and excreted.[170] Its maximal serum concentration (C_{max}) occurs at approximately 1 hour, and its half-life is 1 hour. Repaglinide is highly (>98%) protein bound (volume of distribution, 31 L). It is completely metabolized (via cytochrome P-450 [CYP] 3A4 and 2C8) by the liver to inactive products, with 90% excreted in the feces and 8% excreted in urine. Nateglinide has a bioavailability of 73%.[171] It is rapidly absorbed, with a C_{max} occurring within 1 hour after dosing and a half-life of 1.5 hours. Nateglinide is metabolized (CYP 2C9, 70%; CYP 3A4, 30%) to less-potent compounds, which are 75% excreted in the urine and 10% in the feces. Sixteen percent is excreted unchanged in the urine. It is highly (98%) protein bound, primarily to albumin, and, to a lesser extent, to α_1-acid glycoprotein.

ADVERSE EFFECTS

Mild hypoglycemia may occur, particularly if patients delay or forget to eat after the dose. A weight gain of 0.9 to 3 kg compared with baseline has been observed.[170,171] Rare side effects include elevated hepatic enzymes and hypersensitivity reactions. There has been at least one case report of repaglinide-induced hepatic toxicity.[172]

CONTRAINDICATIONS AND PRECAUTIONS

Because a functioning pancreas is required, these agents should not be used in people with Type 1 diabetes. They should be used with caution in patients with liver dysfunction. They are contraindicated for use in patients with DKA. Repaglinide clearance is reduced in patients with severe renal insufficiency, but may still be used safely at a reduced dose.[170] The clearance of nateglinide is not affected in patients with moderate-to-severe renal insufficiency.[171]

Table 53-25

Comparative Pharmacology of Antidiabetic Agents

Agent/Generic Name (Brand Name)/Mechanism	FDA Indications	A1C Efficacy[a]	Adverse Effects	Comments
Insulin Replaces or augments endogenous insulin	Monotherapy; combined with any oral agent	↓ A1C[b] ↓FPG[b] ↓ PPG[b] ↓ TG	Hypoglycemia, weight gain, lipodystrophy, local skin reactions	Offers flexible dosing to match lifestyle and glucose concentrations. Rapid onset. Safe in pregnancy, renal failure, and liver dysfunction. Drug of choice when patients do not respond to other antidiabetic agents
Insulin-Augmenting Agents				

Nonsulfonylurea secretagogues (glinides) Repaglinide (Prandin) Nateglinide (Starlix) Stimulates insulin secretion	Monotherapy; combined with metformin or TZD	Monotherapy: ↓ A1C ˜1% (repaglinide) ↓ A1C ˜0.5% (nateglinide) Combination: additional 1% ↓ A1C	Hypoglycemia, weight gain	Take only with meals. If a meal is skipped, skip a dose. Flexible dosing with lifestyle. Safe in renal and liver failure. Rapid onset. Useful to lower PPG
Sulfonylureas Various; see Table 53-26. Stimulates insulin secretion. May decrease hepatic glucose output and enhance peripheral glucose utilization	Monotherapy; combined with metformin; combined with insulin (glimepiride)	Monotherapy: ↓ A1C ˜1% Combination: additional 1% ↓ in A1C	Hypoglycemia, especially long-acting agents; weight gain (5–10 lb); rash, hepatotoxicity, alcohol intolerance, and hyponatremia rare	Very effective agents. Some can be dosed once daily. Rapid onset of effect (1 week)
Incretin-Based Therapies				
Glucagon-like peptide-1 receptor agonists/incretin mimetic Exenatide (Byetta) Extended-release exenatide (Bydureon) Liraglutide (Victoza) Dulaglutide (Trulicity) Albiglutide (Tanzeum) Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety	Monotherapy (exenatide only) Combined with metformin, SFU, or TZD; combined with metformin + SFU; combined with metformin + TZD Exenatide and liraglutide can be used in combination with basal insulin	Monotherapy: ↓ A1C 0.8%–0.9% Combination: additional 1% ↓ in A1C	GI: nausea, vomiting, diarrhea; hypoglycemia (with SFUs); weight loss; reports of acute pancreatitis; URTIs	Weight loss. Exenatide: take within 60 minutes before morning and evening meals or before 2 main meals of the day (≥6 hours apart). Liraglutide, extended-release exenatide, dulaglutide, albiglutide: Do not use if personal or family history of medullary thyroid carcinoma (MTC) or in patients with multiple endocrine neoplasia syndrome type 2. Do not use in patients with gastroparesis or severe GI disease. Administered by SC injection; pen device in use does not need to be refrigerated. Rare cases of pancreatitis
DPP-4 inhibitors Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin	Monotherapy; combined with metformin, SFU, or TZD; insulin	Monotherapy: ↓ A1C 0.5%–0.8% Combination: ↓ A1C 0.5%–0.9%	Headache, nasopharyngitis, hypoglycemia (with SFU), rash (rare)	Dosed once daily. Taken with or without food. No weight gain or

(Tradjenta) Alogliptin (Nesina) Stimulates insulin secretion and reduces postprandial glucagon levels	(sitagliptin, linagliptin, and saxagliptin)			nausea. Need to adjust sitagliptin, saxagliptin, and alogliptin dose in renal dysfunction. Reduce dose of SFU when combined. Rare reports of pancreatitis

---

Amylin Receptor Agonists				
Amylin mimetic Pramlintide (Symlin)	Type 1: Adjunct to mealtime insulin	T1: ↓ A1C 0.33% T2: ↓ A1C 0.40%	GI: nausea, decreased appetite	Take only immediately before meals; administered by SC injection. Do not use in patients with gastroparesis. Reduce dose of mealtime insulin by 50% to avoid hypoglycemia when starting therapy
Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety	Type 2: Adjunct to mealtime insulin; ± SFU and metformin		Headache; hypoglycemia; weight loss (mild)	
Insulin Sensitizers				
Biguanides Metformin (Glucophage) ↓ Hepatic glucose output; ↑ peripheral glucose uptake	Monotherapy; combined with SFU or TZD; or with insulin	Monotherapy: ↓ A1C ~1% Combination: additional 1% ↓ in A1C	GI: nausea, cramping, diarrhea; lactic acidosis (rare)	Titrate dose slowly to minimize GI effects. No hypoglycemia or weight gain; weight loss possible. Mild reduction in cholesterol. Do not use in patients with renal or severe hepatic dysfunction
Thiazolidinediones Rosiglitazone (Avandia) Pioglitazone (Actos) Enhances insulin action in periphery; increases glucose utilization by muscle and fat tissue;	Monotherapy; combined with SFU, TZD, or insulin; combined with SFU + TZD	Monotherapy: ↓ A1C ~1% Combination: additional 1% ↓ in A1C	Mild anemia; fluid retention and edema, weight gain, macular edema, fractures (in women)	Can cause or exacerbate HF; do not use in patients with symptomatic HF or class III or IV HF. Rosiglitazone may increase risk of MI. Increased risk of distal fractures in

decreases hepatic glucose output				older women. Pioglitazone may increase risk of bladder cancer when used for >1 year. Slight reduction in TG with pioglitazone; slight increase in LDL-C with rosiglitazone. LFTs must be measured at baseline and periodically thereafter. Slow onset (2–4 weeks)
Glucose Reabsorption Inhibitors				
Sodium–Glucose Cotransporter Type 2 Inhibitors Canagliflozin (Invokana) Dapagliflozin (Farxiga) Empagliflozin (Jardiance) Selectively and reversibly bind to SGLT-2 preventing reabsorption of glucose leading to the excretion of glucose in the urine	May be used as 2nd or 3rd line agent or 1st line in patients who cannot tolerate metformin.	↓A1C 0.7-1.0% ↓FPG ↓PPG May cause weight loss	Genital mycotic infections Urinary tract infections ↓GFR in patients with renal failure	Low risk of hypoglycemia Contraindicated in renal failure GFR<30

Delayers of Carbohydrate Absorption				
α-Glucosidase inhibitors Acarbose (Precose) Miglitol (Glyset) Slow absorption of complex carbohydrates	Monotherapy; combined with SFUs, metformin, or insulin	Monotherapy: ↓ A1C ˜0.5% Combination: additional ˜0.5% ↓ A1C	GI: flatulence, diarrhea. Elevations in LFTs seen in doses >50 mg TID of acarbose	Useful for PPG control (↓ PPG 25–50 mg/dL). LFTs should be monitored every 3 months during the first year of therapy and periodically thereafter. Because miglitol is not metabolized, monitoring of LFTs is not required. Titrate dose slowly to minimize GI

				effects. No hypoglycemia or weight gain. If used in combination with hypoglycemic agents, advise patients to treat hypoglycemia with glucose tablets because absorption is not inhibited as with sucrose. Avoid use in patients with GI disorders (IBD, Crohn disease, intestinal obstruction)
Bile acid sequestrant Colesevelam (Welchol)	Combined with metformin, SFU, or insulin	↓ A1C 0.3%–0.4%	Constipation, dyspepsia, and nausea; ↑ TG	Added benefit of ↓ LDL-C (by 12%–16%). Administer certain drugs 4 hours before. Take with a meal and liquid
Enhancers of Dopaminergic Tone				
Bromocriptine (Cycloset)	Monotherapy; combined with SFU or metformin in patients with type 2 diabetes	Monotherapy ↓ A1C 0.1%; Combo: ↓ A1C 0.5%	Hypotension, dizziness, syncope, nausea, somnolence, headache, exacerbation of psychotic disorders	Very limited role as a therapeutic agent

[a]Comparative effectiveness data provided for SFUs, glinides, TZDs, and α-glucosidase inhibitors.[256]
Theoretically, unlimited glucose lowering with insulin therapy.
A1C, glycosylated hemoglobin; DPP-4, dipeptidyl peptidase-4; FDA, Food and Drug Administration; FPG, fasting plasma glucose; GI, gastrointestinal; HF, heart failure; LDL-C, low-density lipoprotein cholesterol; LFTs, liver function tests; MI, myocardial infarction; PPG, postprandial glucose; SC, subcutaneously; SFU, sulfonylureas; TG, triglycerides; TID, 3 times a day; T1, type 1 diabetes; T2, type 2 diabetes; TZD, thiazolidinediones.

DRUG INTERACTIONS

Clinically relevant drug interactions include those that occur when these drugs are taken in combination with other glucose-lowering agents or drugs known to induce or inhibit their metabolism.[173] Therefore, BG levels should be closely monitored when either drug is taken in combination with other agents known to lower BG or affect their metabolism. Repaglinide is metabolized by CYP 2C8 and 3A4.[170] Studies have shown that repaglinide has no pharmacokinetic effects on digoxin or warfarin. Gemfibrozil should be avoided in combination with repaglinide owing to the risk of hypoglycemia. The combination of gemfibrozil and itraconazole synergistically inhibits repaglinide metabolism and should be avoided. Concomitant use of clopidogrel may result in increased serum concentrations of repaglinide; therefore, dose reduction of repaglinide may be required. Cyclosporine inhibits the metabolism of repaglinide causing increased serum concentrations of repaglinide; therefore, a dose reduction may be required. Nateglinide is metabolized largely by CYP 2C9 (70%) and to a lesser extent by 3A4 (30%).[171] When evaluated in clinical studies, there were no clinically relevant interactions with nateglinide and glyburide, metformin, digoxin, diclofenac, or warfarin. Concomitant use of oral systemic azole antifungals should be used cautiously due to potential for increased hypoglycemic effects. Fibric acid derivatives including fenofibrate, clofibrate, and gemfibrozil may increase the effects of nateglinide. Concomitant use of either repaglinide or nateglinide with rifampin may lower their efficacy.[173]

EFFICACY

The efficacy of repaglinide is comparable to metformin and the sulfonylureas.[174] When used as monotherapy, the mean decrease in FPG, postprandial glucose, and the A1C values were 61 mg/dL, 104 mg/dL, and 1.7%, respectively, compared with placebo (−31.0

mg/dL, −47.6 mg/dL, and −0.6% compared with baseline).[170] Nateglinide as monotherapy results in a mean decrease in FPG and A1C of 13.6 mg/dL and 0.7%, respectively, compared with placebo (−4.5 mg/dL and −0.5% compared with baseline).[171] In comparison with metformin monotherapy, both drugs produce a similar or slightly smaller reduction in A1C.

DOSAGE AND CLINICAL USE

Repaglinide and nateglinide are approved to treat people with Type 2 diabetes as monotherapy or in combination with metformin or a TZD.[170,171] Because they have the same mechanism of action as the sulfonylureas, combining these agents does not produce any additional benefit. The agents are usually added to therapy for patients with postprandial hyperglycemia, particularly nateglinide. When repaglinide is used as the initial treatment in patients who are naïve to oral antidiabetic therapy or in patients with A1C values less than 8%, the recommended starting dose is 0.5 mg 15 to 30 minutes prior to eating up to 4 times a day. When used in patients who have failed sulfonylureas or in those with A1C values greater than 8%, the initial dose is 1 to 2 mg with each meal up to 4 times a day. Doses can be titrated weekly at a rate of 1 mg/meal to a maximum of 4 mg/dose or 16 mg/day. Repaglinide should be initiated at a 0.5-mg dose in patients with severe renal dysfunction and should be titrated cautiously in patients with liver dysfunction. The recommended starting dose of nateglinide is 120 mg TID 0 to 30 minutes before meals. For patients close to their A1C goal, a dose of 60 mg TID may be used. Doses should be omitted if a meal is skipped and added if an extra meal is ingested (repaglinide only). There are no dosage adjustments required for nateglinide in patients with renal or hepatic insufficiency.[170,171]

Sulfonylureas

Until metformin and other antidiabetic agents became available in the United States, sulfonylureas were the first-line pharmacologic treatment for people with Type 2 diabetes who had failed diet and exercise therapy. Six sulfonylureas are available in the United States. The three first-generation sulfonylureas (chlorpropamide, tolazamide, and tolbutamide) are considered equally effective despite differences in their pharmacokinetic properties and adverse effect profiles (see the following discussion and Tables 53-25 and 53-26).

Glipizide and glyburide, two second-generation sulfonylureas, were first introduced into the United States in May 1984. Glimepiride was approved for use in 1995. Despite being approximately 100 times more potent than the first-generation sulfonylureas on a milligram-for-milligram basis, these agents are not more clinically effective. Their duration of activity allows for once- or twice-daily dosing.

Table 53-26

Antidiabetic Pharmacokinetic Data

Drug (Brand Name), Available Tablet Strengths (mg)	Typical Dosing Regimen (mg)	Usual Minimum and Maximum Total Daily Dose (TDD)/How Divided	Mean Half-Life	Approximate Duration of Activity	Bioavailability, Metabolism, and Excretion	Comments
α-Glucosidase Inhibitors						
Acarbose (Precose) 25, 50, 100 mg	25–100 mg with first bite of each meal Begin with 25 mg; ↑ by 25 mg/meal every 4–8 weeks	Minimum: 25 mg TID Maximum dose is 50 mg TID if ≤60 kg; 100 mg TID if >60 kg	2 hours	Affects absorption of complex carbohydrates in a single meal	F = 0.5%–1.7%; extensively metabolized by GI amylases to inactive products; 50% excreted unchanged in the feces	Titrate doses slowly to avoid GI effects
Miglitol (Glyset) 25, 50, 100 mg	25–100 mg with first bite of each meal	Minimum: 25 mg TID Maximum:	2 hours	Affects absorption of complex	Dose of 25 mg is completely absorbed; dose	

	Begin with 25 mg; ↑ by 25 mg/meal every 4–8 weeks	100 mg TID		carbohydrates in a single meal	of 100 mg 50%–70% absorbed; elimination by renal excretion as unchanged drug	
Biguanides						
Metformin (Glucophage) 500, 850, 1000 mg; 500 mg/mL liquid	Begin with 500 mg daily or BID; ↑ by 500 mg daily every 1–2 weeks	0.5–2.5 g BID or TID	Plasma, 6.2 hours. Whole blood, 17.6 hours	6–12 hours	F = 50%–60%; excreted unchanged in urine	Take with food. Avoid in patients with renal dysfunction or those who could be predisposed to lactic acidosis (e.g., alcoholism, severe HF, severe respiratory disorders, liver failure)
Metformin extended-release (Glucophage XR) 500, 750, 1000 mg	500–1,000 mg daily with evening meal; ↑ by 500 mg every 1–2 weeks	1,500–2,000 mg daily	As for metformin, but active drug is released slowly	24 hours	As for metformin	As for metformin
Nonsulfonylurea Insulin Secretagogues (Glinides)						
Repaglinide (Prandin) 0.5, 1, 2 mg	If A1C is <8% or if this is first drug, begin with 0.5 mg with each meal. For others, begin with 1–2 mg/meal	0.5–4 mg with each meal (16 mg/d) TID or QID	1 hour	C_{max} is at 1 hour; duration is approximately 2–3 hours	F = 56%; 92% metabolized to inactive products by the liver; 8% excreted as metabolites unchanged in the urine	Take only with meals. Skip dose if meal is skipped. Maximum dose per meal is 4 mg
Nateglinide (Starlix) 60, 120 mg	120 mg TID 1–30 minutes before meals; 60 mg TID for patients with near-normal A1C at initiation	60 or 120 mg TID	1.5 hours	Onset, 20 minutes; peak, 1 hours; duration, 2–4 hours	F = 73%; metabolized to inactive products (predominantly) that are excreted in the urine (83%) and feces (10%)	Skip dose if meal is skipped
First-Generation Sulfonylureas						
Acetohexamide (Dymelor) 250, 500 mg	250 or 500 mg daily; ↑ by 250 mg	0. 25–1.5 g daily or BID	5 hours (active metabolite)	12–18 hours	Activity of metabolite greater then	Caution in elderly and patients with

	daily every 1–2 weeks				parent drug. Metabolite excreted, in part, by kidney	renal disease. Significant uricosuric effects
Chlorpropamide (Diabinese) 100, 250 mg	100 or 250 mg daily; ↑ by 100 or 250 mg every 1–2 weeks	0.1–0.5 g daily	≥35 hours	24–72 hours	Inactive and weakly active metabolites; 20% excreted unchanged; varies widely	Caution in elderly and patients with renal impairment. Highest frequency of side effects relative to other sulfonylureas
Tolazamide (Tolinase) 100, 250, 500 mg	100–250 mg daily; ↑ by 100 or 250 mg every 1–2 weeks	0.2–1 g daily or BID	7 hours (4–25)	12–24 hours	Some metabolites with moderate activity excreted via kidney	Active metabolites may accumulate in renal failure
Tolbutamide (Orinase) 250, 500 mg	250 mg BID before meals; ↑ by 250 mg daily every 1–2 weeks	0.5–3 g BID or TID	7 hours	6–12 hours	Metabolized to compounds with negligible activity	No special precautions Shortest-acting sulfonylurea
Second-Generation Sulfonylureas						
Glimepiride (Amaryl) 1, 2, 4 mg	1–2 mg daily initially; usual maintenance dose is 1–4 mg	1–8 mg daily	9 hours	24 hours	F = 100% completely metabolized by liver. Principal metabolite is slightly active (30% of parent compound). Excreted by the urine (60%) and feces (40%)	Probably safe in patients with renal failure, but low initial doses recommended for older patients and those with renal insufficiency. Incidence of hypoglycemia may be lower than other long-acting sulfonylureas

Glipizide (Glucotrol) 5, 10 mg	2.5 mg daily in elderly, 5 mg daily in others;	2.5–40 mg daily or BID[a]	2–4 hours	12–24 hours	Metabolized to inactive compounds	No special precautions daily dose >15

	↑ by 2.5 or 5 mg every 1–2 weeks					mg should be divided. Dose 30 minutes before meals
Glipizide extended-release (Glucotrol XL) 5 mg	5 mg daily; ↑ by 5 mg every 1–2 weeks	5–20 mg daily	4–13 hours	24 hours	Same as glipizide	Use with caution in patients with preexisting GI narrowing owing to possible obstruction
Glyburide (Diabeta, Micronase) 1.25, 2.5, 5 mg	1.25 mg daily in elderly, 2.5 mg daily in others; ↑ by 1.25 or 2.5 mg every 1–2 weeks	1.25–20 mg daily or BID	4–13 hours	12–24 hours	Metabolized to inactive or weakly inactive compounds; 50% excreted in urine and 50% in feces.	Caution in elderly patients with renal failure and others predisposed to hypoglycemia. Daily doses >10 mg should be divided
Micronized glyburide (Glynase PresTab) 1.5, 3 mg	1.5 mg daily; ↑ by 1.5 mg every 1–2 weeks	1.0–12 mg daily	4 hours	24 hours	Metabolized to inactive or weakly inactive compounds; 50% excreted in urine and 50% in feces.	Daily doses >6 mg should be divided. ↑ Bioavailability relative to original formulation. Resulted in reduced dose
Thiazolidinediones						
Rosiglitazone (Avandia) 2, 4, 8 mg	4 mg daily; ↑ to 8 mg daily (or 4 mg BID)	4–8 mg daily in single or divided doses	3–4 hours	Onset and duration poorly correlated with half-life because of mechanism of action. Onset at 3 weeks; max at ≥4 weeks. Offset likely to be similar	F = 99%; extensively metabolized in liver into inactive metabolites; excreted 2/3 in urine and 1/3 in feces.	Food has no effect on absorption. BID dosing may have greater A1C lowering effect. No dose adjustments required in renal failure. Avoid in patients with liver disease and heart failure
Pioglitazone (Actos) 15, 30, 45 mg	15–30 mg daily; ↑ to 45 mg daily. If	15–45 mg daily	3–7 hours (16–24 hours for all	Same as previous	Extensively metabolized in liver; 15%–	Food delays absorption but is not

	used with insulin, ↓ insulin dose by 10%–25% once FPG <120 mg/dL		metabolites)		30% excreted in urine, remainder eliminated in the feces	clinically significant. No dose adjustments required in renal disease. Avoid in patients with liver disease and heart failure
GLP-1 Receptor Agonists/Incretin Mimetics						

Exenatide (Byetta)	5 mcg SC BID; ↑ to 10 mcg SC BID after 1 month	5–10 mcg BID	2.4 hours	C_{max} is at 2.1 hours; duration 10 hours	Glomerular filtration	Take within 60 minutes before morning and evening meal. Nausea usually subsides with time
Exenatide ER (Bydureon)	2mg SC once weekly	2 mg once weekly	10 weeks	Initial Cmax is at 2 weeks, second peak is at 6 to 7 weeks	Glomerular filtration	Take daily without regard to meals. Nausea usually subsides with time.
Liraglutide (Victoza)	0.6 mg daily for 1 week; ↑ to 1.2 mg daily	0.6–1.8 mg daily	13 hours	24 hours; C_{max} is 8–12 hours after dosing	Metabolized as other large proteins	Take daily without regard to meals. Nausea usually subsides with time
Dulaglutide (Trulicity)	0.75 mg SC once weekly; can ↑ to 1.5 mg once weekly	0.75–1.5 mg weekly	Approximately 5 days	Cmax is at 48 hours	Degraded into amino acids by protein catabolism	Take daily without regard to meals. Nausea usually subsides with time
Albiglutide (Tanzeum)	30 mg SC once weekly;	30–50 mg weekly	Approximately 5 days	Cmax is at 3 to 5 days	Metabolized by ubiquitous	Take daily without

	can ↑ to 50 mg once weekly			after administration	proteolytic enzymes into small peptides and amino acids	regard to meals. Nausea usually subsides with time
DPP-4 Inhibitors						
Sitagliptin (Januvia)	100 mg daily CrCl ≥30 to <50 mL/minute: 50 mg daily CrCl <30 mL/minute: 25 mg daily	100 mg daily	12.4 hours	24 hours	F = 87%; 79% excreted unchanged in urine	Requires dose adjustment in renal insufficiency
Saxagliptin (Onglyza)	5 mg daily CrCl ≤50 mL/min: 2.5 mg daily	2.5–5 mg daily	2.5 hours (3.1 hours for active metabolite)	24 hours	Metabolized by CYP 3A4/5 Excreted by renal and hepatic pathways	Active metabolite is ½ as potent Reduce dose to 2.5 mg with strong CYP 3A4/5 inhibitors
Linagliptin (Tradjenta)	5 mg daily	5 mg daily	12 hours	24 hours	F = 30%; 90% excreted unchanged (80% enterohepatic system, 5% urine). Small fraction metabolized to inactive metabolite	No dose adjustment needed in liver or renal disease

Alogliptin (Nesina)	25 mg daily CrCl 30 to 59 mL/minute: 12.5 mg daily CrCl <30 mL/minute: 6.25mg daily	25 mg daily	21 hours	24 hours	F=100%, 76% excreted unchanged and 13% eliminated in feces. Small fraction metabolized to inactive metabolite	Requires dose adjustment in renal insufficiency
Amylin Mimetics						
Pramlintide (Symlin)	Type 1 DM: 15 mcg SC	Type 1: 15–60 mcg	48 minutes	C_{max} is 20 minutes	F = 30%–40%;	Reduce mealtime

	before major meals; ↑ by 15-mcg increments after minimum of 3 days	before major meals			metabolized by kidneys	insulin dose by 50%. Titrate dose if no significant nausea
	Type 2 DM: 60 mcg SC before major meals; ↑ to 120 mcg after 3–7 days	Type 2: 60 or 120 mcg before major meals				
SGLT-2 Inhibitors						
Canagliflozin (Invokana)	100 mg by mouth before first meal	May increase to 300 mg daily	10.6 hours		F = ˜65% Metabolism: Primarily UGT1A9 and UGT2B4. ˜7% Metabolized through CYP3A4	
Dapagliflozin (Farxiga)	5 mg by mouth daily before first meal	May increase to 10 mg daily	12.9 hours		F = 78% Metabolism: Primarily (UGT) isoenzyme 1A9.	
Empagliflozin (Jardiance)	10 mg by mouth daily before first meal	May increase to 25 mg daily	12.4 Hours		Metabolism: Primarily through glucuronidation by UGT2B7, UGT1A3, UGT1A8, UGT1A9	
Bile Acid Sequestrants						
Colesevelam (Welchol)	6 tablets once daily or 3 tablets BID [625 mg tablets]	3.75 g	N/A	N/A	Drug is not absorbed systemically and not metabolized	Take with food and liquid. Do not use if history of bowel obstruction, TG >500 mg/dL, or history of pancreatitis from ↑ TG.

Enhancers of Dopaminergic Tone						
Bromocriptine (Cycloset), 0.8 mg	1.6–4.8 mg once daily in the morning; Begin with 0.8 mg daily and increase by 1 tablet each week until max tolerated dose	1.6–4.8 mg daily	6 hours		F = 65%–95% Metabolized extensively by CYP3A4; 93% undergoes first-pass metabolism Excreted primarily in bile; 2%–6% in urine	Take with food to reduce GI side effects. Food increases AUC. Highly protein bound

A1C, glycosylated hemoglobin; BID, 2 times a day; C_{max}, maximal concentration; CrCl, creatinine clearance; CYP, cytochrome P-450; DM, diabetes mellitus; DPP-4, dipeptidyl peptidase-4; F, bioavailability; FPG, fasting plasma glucose; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; HF, heart failure; N/A, not available; QID, 4 times a day; SC, subcutaneously; TG, triglycerides; TID, 3 times a day.

MECHANISM OF ACTION

Sulfonylureas stimulate the release of insulin from pancreatic β-cells and enhance β-cell sensitivity to glucose. A specific sulfonylurea receptor closely linked to the ATP-sensitive potassium ion channel exists on the β-cell. Sulfonylureas inhibit this potassium ion channel, thus blocking the efflux of potassium and lowering the membrane potential to cause depolarization. The voltage-dependent calcium channels then open, increasing intracellular calcium concentration. The increased intracellular concentration of calcium ultimately stimulates preformed insulin secretion. Additionally, sulfonylureas can normalize hepatic glucose production and enhance peripheral glucose disposal.[63,175]

PHARMACOKINETICS

The duration of hypoglycemic activity is related to the half-life of these compounds only in very general terms and may correlate poorly in some cases.[176] All sulfonylureas are highly protein bound (90%–100%), mainly to albumin. Binding characteristics, however, vary among individual sulfonylureas. Food does not impair the extent of drug absorption, but may delay the time to peak levels of some agents. The relationship between sulfonylurea doses and their BG-lowering effect remains unclear. Studies of glyburide and glipizide suggest that these agents may operate within a narrow range of plasma concentrations that may be achieved with low (10 mg/day) doses.[177–179] The maximal recommended daily doses of 40 mg for glipizide and 20 mg for glyburide may therefore not be more effective and may decrease β-cell function.[179]

Glipizide is an intermediate-acting second-generation agent with a half-life of 2 to 4 hours, but a duration of action of 12 to 24 hours. Patients receiving less than 20 mg/day may require only once-daily dosing. Food delays its rate of absorption, but not its bioavailability. Glipizide should be taken 30 minutes before meals. The onset of action occurs in 90 minutes, and the maximum decrease in serum glucose occurs within 2 to 3 hours. Glipizide is extensively metabolized by the liver to inactive products that are eliminated primarily by the kidney.[176] An extended-release formulation of glipizide also is available.

Glyburide is a longer-acting second-generation agent similar to glipizide. The half-life is approximately 1.5 to 4 hours after single-dose studies and up to 13.7 hours when chronically administered.[180] Nevertheless, as with glipizide, the duration of action can last for up to 24 hours in many patients, allowing for once-daily dosing with small-to-intermediate doses (<15 mg). Food does not delay the rate or extent of absorption. The onset of action is 2 hours, and the maximum decrease in serum glucose occurs within 3 to 4 hours. Glyburide is metabolized completely by the liver to two weakly active metabolites, half of which are excreted in the urine and feces. A micronized formulation is available (e.g., Glynase PresTab), but it is not bioequivalent to the conventionally formulated tablets. Thus, patients switched between the conventional form and the micronized product must be carefully monitored and the dose titrated again.

Glimepiride is a long-acting second-generation sulfonylurea. Its half-life is 9 hours and its duration of action is 24 hours, allowing for once-daily dosing.[181] The administration of glimepiride with food slightly decreases the AUC and slightly increases the time to peak concentration. Its peak effect on plasma glucose concentrations is observed 2 to 3 hours after each dose. Glimepiride is completely metabolized by the liver, and its principal metabolite has 30% of the activity of the parent drug. Metabolites are excreted in feces and urine. Interestingly, research suggests that the sulfonylureas may close ATP-sensitive potassium channels in cardiac tissue, similar to their action at the β-cell. In the heart, this effect could prevent vasodilation during an ischemic episode (i.e., ischemic preconditioning).[182]

ADVERSE EFFECTS

The primary side effects of the sulfonylureas are hypoglycemia (particularly for those that are long-acting, see Case 53-16, Question 2, and Case 53-18, Question 6) and weight gain (~2 kg).[114] Other adverse effects attributed to the sulfonylureas generally are so infrequent and mild that fewer than 2% of patients discontinue these agents because of them. In general, the type, incidence, and severity of reported side effects are similar for all the sulfonylureas. An important exception is chlorpropamide, which has several unique adverse effects (see following discussion). Adverse reactions to the sulfonylureas include GI symptoms (nausea, fullness, bloating that can be relieved if taken with meals), rare blood dyscrasias, allergic dermatologic

---

reactions and photosensitivity, hepatotoxicity, and hyponatremia (also see Case 53-16).[161]

A disulfiram (Antabuse-like) reaction occurs when patients take certain sulfonylureas (primarily chlorpropamide, occurring in approximately one-third of patients receiving it) and drink ethanol. The flushing reaction is rare with other sulfonylureas.

The syndrome of inappropriate secretion of antidiuretic hormone can occur with chlorpropamide and, to a lesser extent, with tolbutamide, but these agents are rarely used in the United States anymore. If it occurs, the syndrome of inappropriate secretion of antidiuretic hormone is a syndrome of enhanced secretion of vasopressin from the pituitary. This results in an increase in the retention of free water by the kidneys and a dilutional hyponatremia. In the UKPDS study, the increase in BP seen in patients on chlorpropamide was likely attributable to water retention.[35] In contrast to chlorpropamide and tolbutamide, glipizide, glyburide, tolazamide, and acetohexamide have a very mild diuretic effect.

CONTRAINDICATIONS AND PRECAUTIONS

Contraindications to the use of sulfonylureas include the following:

1. Type 1 diabetes;
2. Pregnancy or breast-feeding, because these agents (except glyburide) can cross the placental barrier and can be excreted into breast milk;
3. Documented hypersensitivity to sulfonylureas;
4. Severe hepatic or renal dysfunction;
5. Severe, acute intercurrent illness (e.g., infection, MI), surgery, or other stress that can unduly affect BG control, in which case insulin therapy should be used; and
6. G6PD deficiency—Patients with this deficiency may be at risk for hemolytic anemia if they take chlorpropamide—consider using a nonsulfonylurea medication as an alternative.

DRUG INTERACTIONS

Drug interactions with sulfonylureas have a pharmacodynamic or pharmacokinetic basis. Pharmacodynamic interactions are discussed later in this chapter in sections addressing drug-induced hypoglycemia and hyperglycemia. Most of the reported pharmacokinetic drug interactions with the sulfonylureas involve chlorpropamide and tolbutamide. Because most of the clinically significant interactions occur with drugs that alter liver metabolism or urinary excretion, possible interactions with all of the sulfonylureas must be anticipated, even though the outcomes may be quite different. Glipizide and glyburide also differ from the first-generation agents in that they are highly bound to albumin at nonionic rather than ionic sites.[176] On this basis, these agents are unlikely to interact with other highly protein-bound drugs, such as phenylbutazone, salicylates, or certain sulfonamide antibiotics that have been reported to enhance the effects of the first-generation sulfonylureas. These highly protein-bound drugs, however, seem to interact with the sulfonylureas by altering their hepatic metabolism as well. Therefore, glipizide and glyburide should be used cautiously with drugs reported to interact with first-generation sulfonylureas. Sulfonylureas are CYP 2C9 substrates; therefore, coadministration with a medication that is an inhibitor or inducer of CPY 2C9 will increase or decrease levels of sulfonylurea medications, respectively.[173]

EFFICACY

Like metformin, the sulfonylureas decrease the A1C by 1.5% to 1.7% and the FPG by 50% to 70%. With time and increased duration of Type 2 diabetes, the pancreas may respond less to a sulfonylurea. Whether sulfonylureas actually contribute to β-cell dysfunction and decline remains to be clearly determined.[183]

DOSAGE AND CLINICAL USE

The sulfonylureas are effective, inexpensive, and easy to titrate. Sulfonylureas are generally used as add-on therapy to patients unable to achieve BG goals on metformin monotherapy. Like the other antidiabetic agents discussed here, sulfonylureas may also be considered as monotherapy in patients with contraindications to metformin therapy. The doses of the sulfonylureas are displayed in Table 53-26. As a general rule, one should begin with low doses and titrate upward every 1 to 2 weeks until the desired goal is achieved. Exceeding maximal doses is not likely to produce improvement, but may put the patient at risk for adverse effects (see Case 53-18, Questions 5 and 6).

Thiazolidinediones

MECHANISM OF ACTION

The two available TZDs in the United States, rosiglitazone and pioglitazone, are often referred to as insulin sensitizers. The precise molecular actions of these agents remain to be clarified. TZDs bind to and activate a nuclear receptor (peroxisome proliferator-activated receptor-γ [PPAR-γ]), which is expressed in many insulin-sensitive tissues, including adipose (major site), skeletal muscle, and liver tissue.[184] PPAR-γ regulates transcription of genes that influence glucose and lipid metabolism. For example, PPAR-γ stimulation increases the transcription of GLUT-4, a glucose transporter that stimulates glucose uptake.[185] Reduced expression of GLUT-4 may contribute to the development of insulin resistance. Pioglitazone activates PPAR-α in addition to PPAR-y, which inhibits the transcription of tumor necrosis factor-α-induced vascular cell adhesion molecule (VCAM-1).[185] This duel effect by pioglitazone enables HDL to be raised and triglycerides to be lowered. PPAR-α activation is involved in actions that are anti-inflammatory and the PPAR-y and -α activation can improve insulin sensitivity and lipid profiles.[186]

TZDs either directly or indirectly sensitize adipose tissue to insulin action.[175,184] The effects may include stimulating apoptosis of large adipocytes, increasing the number of small adipose cells, and promoting fatty acid uptake and storage in adipose tissue. The subsequent reduction in free circulating fatty acids may spare other insulin-sensitive tissues (e.g., liver, skeletal muscle, β-cells) from the effects of lipotoxicity. TZDs also lower expression of tumor necrosis factor-α, a cytokine produced by adipose tissue that may contribute to insulin resistance and fatty acid release.[175,184] Other adipokines are likely involved, including adiponectin, resistin, and leptin.[175] TZD interaction with adipocytes may be their primary mechanism of action in sensitizing other tissues to insulin action. As with metformin, TZDs have been shown to directly stimulate the AMPK pathway in liver and adipose tissue, resulting in a lowering of glucose and free fatty acids.[164,184]

Other observed effects of TZDs that may be beneficial in patients with Type 2 diabetes and metabolic syndrome include favorable effects on triglycerides, reduction of inflammatory mediators, inhibition of vascular smooth muscle cell proliferation, improved endothelial function, lowering microalbumin excretion, and enhanced fibrinolysis.[175,184] Despite these apparently favorable effects on surrogate measures of vascular disease, the data regarding TZDs and vascular risk are mixed and controversial. In 2009, the FDA added language to the label for rosiglitazone indicating an increased risk of angina and MI. The Food and Drug Administration and GlaxoSmithKline instituted a Risk Evaluation and Management Strategy (REMS) to restrict the distribution and prescribing of rosiglitazone; however, in May, 2014, the REMS was changed to allow for the prescribing and filling of prescriptions of rosiglitazone.

In summary, the TZDs clinically decrease insulin resistance in muscle and liver, which enhances glucose utilization and decreases hepatic glucose output. They have favorable effects on markers of vascular disease such as triglycerides and inflammatory cytokines.

PHARMACOKINETICS

Rosiglitazone is completely absorbed, with peak plasma concentrations reached in approximately 1 hour.[187] Pioglitazone has a bioavailability of 83%, with peak plasma concentrations reached within 2 hours.[185] Food delays the time to peak concentration, but does not alter the extent of absorption of either drug. Both TZDs are extensively (>99%) protein bound, primarily to albumin. The plasma elimination half-life of rosiglitazone is 3 to 4 hours.[187] Pioglitazone has a serum half-life of 3 to 7 hours, and its metabolites have a serum half-life of 16 to 24 hours.[185] Rosiglitazone is extensively metabolized in the liver by CYP 2C8 and to a much lesser extent by 2C9. Its conjugated metabolites are considerably less potent than the parent drug and are excreted two-thirds in urine and one-third in feces.[187] Pioglitazone is hepatically metabolized, mainly by CYP 2C8 and 3A4, and to a lesser degree by CYP 1A1, to three active metabolites; however, the main metabolites found in serum are M-III and M-IV. Approximately 15% to 30% of the dose is recovered in the urine as metabolites, with the remainder excreted either into the bile as unchanged drug or into the feces as metabolites.[184,185]

Because the action of the TZDs relies on gene transcription and protein production, the onset and duration of action are unrelated to the plasma half-life. The onset of their effect occurs in 1 to 2 weeks, although maximal effects are not usually seen before 8 to 12 weeks. No dose adjustment is necessary in patients with renal impairment. There is no dose adjustment needed for hepatic impairment with pioglitazone; however, rosiglitazone should be avoided in patients with moderate-to-severe hepatic impairment.[185,187]

ADVERSE EFFECTS

Hepatotoxicity

Liver failure has been very rarely reported with either rosiglitazone or pioglitazone, although causality in most cases remains uncertain.[188–190] For both drugs, monitoring of liver function tests (LFTs) is recommended at baseline, and then periodically thereafter (see Contraindications and Precautions section). Many practitioners check the LFTs every 3 to 6 months during the first year of therapy and then every 6 to 12 months thereafter.

Hematologic Effects

TZD therapy may result in small decreases in hemoglobin and hematocrit and, infrequently, anemia.[175,184] These effects may be attributable to dilutional effects (see below).

Weight Gain

Dose-related weight gain (2–3 kg for every 1% decrease in A1C) has been seen with rosiglitazone and pioglitazone.[184] Weight gain is likely caused by fluid retention or fat accumulation. The weight gain seems to be associated with an increase in peripheral adipose tissue along with a reduction in visceral adiposity.[175,184]

Vascular and Cardiovascular Effects

Increases in plasma volume and peripheral edema (4%–6%), possibly caused by increased endothelial cell permeability, occur with the TZDs.[184] The incidence of peripheral edema is greatly increased when TZDs are used in combination with insulin.

The FDA added black box warnings to rosiglitazone and pioglitazone based on the association of their use with an increased risk of developing or exacerbating HF in patients with Type 2 diabetes.[185,187] TZDs are contraindicated for use in patients with

NYHA class III or IV HF and are not recommended in patients with acute or systemic HF. Meta-analysis and retrospective observational studies have suggested that rosiglitazone is associated with risk of MI,[191–193] but not for overall cardiovascular or all-cause mortality.[193] Pioglitazone does not appear to increase the risk of MI or mortality.[194–197] TZDs should be used with caution in patients with preexisting edema, which may increase the risk of developing new-onset HF or exacerbating preexisting HF (see Case 53-15).

Other Effects

Hypersensitivity reactions including rash, pruritus, urticaria, angioedema, anaphylactic reaction, and Stevens–Johnson syndrome have been rarely reported with rosiglitazone.[185,187] Macular edema has been rarely reported with TZDs.[185,187,198] Patients experiencing changes or worsening in vision should be referred to an ophthalmologist for follow-up. In some cases, macular edema improved or resolved after discontinuation of TZD therapy.

Pioglitazone has been associated with an increased risk of bladder cancer compared to the general population and is contraindicated in patients with bladder cancer.[199] In patients with previous history of bladder cancer, the need for use of pioglitazone for glycemic control must outweigh the potential recurrence of bladder cancer.[199] The FDA has released a safety communication warning that the use of pioglitazone for longer than 1 year may increase the risk for bladder cancer.[199] Recently analyzed 10-year findings show no statistically significant increase in bladder cancer, but a risk as previously identified cannot be ruled out. This meta-analysis identified a possible increased risk of pancreatic and prostate cancer. Monitoring for causal effect of cancers should be continued.[199]

An increased risk of distal limb bone fractures (e.g., forearm, hand, wrist, foot, and ankle) and bone loss have been observed in women receiving TZDs.[200–203] Men may also be at increased fracture risk, but the evidence is not as strong.[202,203] The mechanism is thought to be reduced osteoblast differentiation as a result of increased adipogenesis in the bone marrow.[204] The potential for fractures in older female patients and patients on chronic steroids should be carefully considered before using a TZD.

CONTRAINDICATIONS AND PRECAUTIONS

- Type 1 diabetes: Because insulin is required for their action, TZDs should not be used in people with type 1 diabetes.
- Patients with type 2 diabetes using insulin: TZDs should be used with caution because of the increased risk of developing edema.
- Preexisting hepatic disease: Pioglitazone and rosiglitazone should not be used in patients whose ALT is more than 2.5 times normal. TZDs should be discontinued if the ALT is more than 3 times normal, if serum bilirubin levels begin to rise, or

if the patient complains of any symptoms that could be attributed to hepatitis (e.g., fatigue, nausea, vomiting, abdominal pain, and dark urine).

- Symptomatic or severe (NYHA classes III and IV) HF: See previous discussion.
- Myocardial ischemia (rosiglitazone only): See previous discussion.
- Premenopausal anovulatory women: TZDs may cause resumption of ovulation and menstruation in women with polycystic ovarian syndrome, placing these patients at risk for an unwanted pregnancy.
- History of hypersensitivity to TZDs.
- Patients with osteoporosis or at risk for bone fractures (e.g., chronic steroid use).
- Drugs metabolized by CYP 3A4: See the Drug Interactions section for further details.
- Patients with a current or previous history of bladder cancer should not use TZDs.
- Macular edema: Patients should receive regular eye examinations to evaluate acut visual changes.

DRUG INTERACTIONS

Coadministration of a TZD with other antidiabetic medications or insulin does not alter the pharmacokinetics of either drug, but may increase the patient’s risk for hypoglycemia. Pioglitazone induces CYP 3A4 and may, therefore, decrease effectiveness of other drugs metabolized by this enzyme, such as estrogens, cyclosporine, tacrolimus, and β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. Ketoconazole may significantly inhibit the metabolism of pioglitazone.[185] Patients taking oral contraceptives or estrogen-replacement therapy should be informed of the possible risk of decreased effectiveness of estrogen therapy. Rosiglitazone does not seem to inhibit any of the major CYP enzymes.[187] Rifampin decreases the area under the plasma concentration–time curve (AUC) for both rosiglitazone and pioglitazone, although the clinical significance of this interaction is unknown. Pioglitazone is a substrate of CYP2C8; therefore, interactions may occur when administered with drugs that inhibit or induce CYP2C8.[205] The maximum dose of pioglitazone is 15 mg once a day if given with a strong CYP2C8 inhibitor.[185] Gemfibrozil significantly increases the AUC of both drugs. For patients receiving both a TZD and a gemfibrozil, a dose reduction of the TZD may be warranted.[205]

EFFICACY

The effects of TZDs on A1C and FPG are intermediate between those of acarbose and the sulfonylureas or metformin.[175,184] When combined with other antidiabetic agents in a poorly controlled type 2 diabetes patient, one can expect to see an augmented effect on the A1C (0.9%–1.3% decrease with a sulfonylurea, 0.8%–1.0% decrease with metformin, and 0.7%–1.0% decrease with insulin).[185,187] When added to the therapy of a type 2 diabetes patient taking insulin, rosiglitazone and pioglitazone can enhance glycemic control (approximately 0.6% lower with pioglitazone) while decreasing insulin requirements; however, weight gain (>3 kg) and increased edema will likely occur.[206] Individuals who are minimally responsive or unresponsive to TZD therapy may include those who are not obese and have lower levels of endogenous insulin.

Other potential benefits of the TZDs are their favorable, but variable, effects on lipids.[184,185,187] Pioglitazone and to a lesser extent rosiglitazone may decrease triglycerides. Both drugs may increase HDL-C levels by 10%. Rosiglitazone has been observed to increase LDL-C by 8% to 16%, whereas pioglitazone may not affect LDL-C. As noted, TZD therapy has been associated with weight gain, and this may be substantial when used in combination with sulfonylureas or insulin.

DOSAGE AND CLINICAL USE

Patients who are unable to take or have failed metformin or sulfonylurea monotherapy or who have not responded to combination therapy with other oral antidiabetic agents are usually candidates for TZD therapy. For monotherapy or combination therapy with a sulfonylurea, metformin, or insulin, the starting dose for pioglitazone is 15 or 30 mg once daily with or without food. The dose can be titrated up to a maximum of 45 mg/day.[185] The starting dose for rosiglitazone is 4 mg given once daily or in divided doses. The dose may be increased after 8 to 12 weeks if adequate response is not seen. The maximum daily dose is 8 mg.[187]

Glucosidase Inhibitors

MECHANISM OF ACTION

The α-glucosidase inhibitors, acarbose[207] and miglitol,[208] reversibly inhibit glucosidases present in the brush border of the mucosa of the small intestine. These enzymes break down complex polysaccharides and disaccharides into glucose and other absorbable monosaccharides. Enzyme inhibition delays carbohydrate digestion and subsequent glucose absorption. Postprandial BG concentrations are therefore lowered when these agents are taken with a meal containing complex carbohydrates.

PHARMACOKINETICS

Acarbose is minimally absorbed from the GI tract, with an oral bioavailability of the parent drug of less than 2.0%.[207] It is extensively metabolized by GI amylases to inactive metabolites. The peak plasma concentration occurs in approximately 1 hour and the elimination half-life for acarbose is 2 hours, although there may be a longer terminal half-life. Unlike acarbose, miglitol is absorbed. Absorption of miglitol is saturable at higher doses (>25 mg) and peak concentration occurs in 2 to 3 hours.[208] The drug is primarily distributed in extracellular fluids and is not metabolized. After a 25-mg dose, 95% of the drug is excreted unchanged by the kidneys within 24 hours.

ADVERSE EFFECTS

Flatulence, diarrhea, and abdominal pain are the most frequently reported adverse effects of α-glucosidase inhibitors.[207,208] In placebo-controlled trials of acarbose, these complaints were experienced by 74%, 31%, and 19% of subjects, respectively. GI side effects are attributable to fermentation of unabsorbed carbohydrate in the small intestine and can be minimized by slowly titrating the dose of either agent. GI discomfort usually improves with continued therapy because induction of the α-glucosidase enzymes occurs in the distal jejunum and terminal ileum.

In studies using doses of acarbose 300 mg/day or more, a transient increase in serum hepatic transaminases was reported.[209] The manufacturer recommends monitoring hepatic transaminases every 3 months for the first year of therapy and periodically thereafter. If an elevation of serum transaminases occurs, the dose should be decreased or discontinued if elevations persist. Because miglitol is not metabolized, it does not seem to affect hepatic function.

CONTRAINDICATIONS AND PRECAUTIONS

Acarbose and miglitol are contraindicated with known hypersensitivity to the medications.[207,208] Both medications are contraindicated in patients with DKA and acarbose is contraindicated in patients with cirrhosis.

Gastrointestinal Conditions

Because of their profound GI effects (flatulence, diarrhea), acarbose and miglitol are contraindicated in patients with malabsorption, inflammatory bowel disease, colonic ulceration or other marked disorders of digestion or absorption, or with intestinal obstruction.[207,208]

Renal Impairment

Acarbose has not been studied in patients with severe renal impairment (SCr >2.0 mg/dL) and should not be used in these patients.[209] There is little information with regard to safety of the use of miglitol in patients with a CrCl<25 mL/minute; therefore, its use is contraindicated in these patients.[207,208]

DRUG INTERACTIONS

Patients who use acarbose or miglitol in combination with other antidiabetic agents may experience hypoglycemia. These reactions should be treated with dextrose because acarbose may limit the availability of the disaccharide sucrose (table sugar). Because acarbose and miglitol delay carbohydrate passage through the bowel, they could influence the absorption kinetics of concomitantly administered drugs.

Conversely, because their own absorption may be diminished by digestive enzyme preparations and charcoal, they should not be taken concomitantly with these agents.[207–209] The bioavailability of digoxin can be reduced and may require dose adjustment. Miglitol decreases the bioavailability of ranitidine and propranolol by 60% and 40%, respectively.[208]

EFFICACY

By delaying the absorption of glucose after ingestion of complex carbohydrates and disaccharides, the α-glucosidase inhibitors can lower postprandial plasma glucose concentrations in patients with type 2 diabetes by 25 to 50 mg/dL.[207,208] FPG concentrations remain unchanged or are slightly lowered (20–30 mg/dL), but this effect may be related to decreased glucose toxicity, which improves insulin secretion and action. Mean A1C values decline by 0.3% to 0.7%. Acarbose and miglitol have no effect on weight or lipid profiles.[207,208]

DOSAGE AND CLINICAL USE

Because of limited effects on A1C and their side effect profile, α-glucosidase inhibitors are used infrequently and, when used, are usually given as add-on therapy in patients who have failed monotherapy or combination therapy with other oral antidiabetic agents. The recommended initial dose of either drug is up to 25 mg TID, taken at the start of each meal.[207,208] The dosage of acarbose can be gradually increased (e.g., 25 mg/meal) every 4 to 8 weeks to a maximum of 50 mg TID for individuals weighing 60 kg or less, or 100 mg TID for individuals weighing more than 60 kg. The dose for miglitol is titrated up after 4 to 8 weeks to a dose of 50 to 100 mg TID if needed, regardless of a patient’s weight. A maximal response is observed at 6 months.

Incretin-Based Therapies

Incretins are insulinotropic hormones secreted from specialized neuroendocrine cells in the small intestinal mucosa in response to carbohydrate ingestion and absorption.[13] The two hormones accounting for most incretin effects are glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1). GIP and GLP-1 stimulate pancreatic β-cells in a glucose-dependent manner, contributing to the early-phase insulin response. GLP-1 also inhibits pancreatic α-cells, thus reducing glucagon secretion and hepatic glucose production. Incretin action is efficient, but short lived. As they enter the blood vessels, incretins undergo rapid metabolism via proteolytic cleavage by dipeptidyl peptidase-4 (DPP-4) to inactive metabolites. Thus, only small amounts are needed to exert their effects on glucose metabolism.

Glucagon-like Peptide-1 Agonists (GLP-1 Mimetics/Analogs)

Exenatide, extended-release exenatide, albiglutide, liraglutide, and dulaglutide are the five available GLP-1 agonists in the United States. The formulations available are a once-daily injection (liraglutide), twice-daily injection (exenatide), and once-weekly injections (extended-release exenatide, albiglutide and dulaglutide).

MECHANISM OF ACTION

GLP-1 mimetics and analogs have stability in the presence of DPP-4, resulting in a longer duration of action than endogenous GLP-1. Exenatide is a synthetic form of exendin-4, a peptide originally discovered from the saliva of the Gila monster.[210] Exendin-4 shares 50% of its amino acid sequence with GLP-1, demonstrating similar affinity for receptor sites but a strong resistance to DPP-4. Liraglutide is a GLP-1 analog that is 97% homologous to human GLP-1, and reversibly binds to plasma albumin owing to the C16 fatty acid side chain, thereby increasing resistance to DPP-4 degradation.[211] Albiglutide has 2 tandem copies of modified human GLP-1 fused to human albumin. The human fragment sequence has been modified to allow for resistance to DPP-IV-mediated proteolysis, and in combination with the human albumin moiety of the fusion protein, the half-life is extended allowing for once-weekly dosing.[212] Dulaglutide is a human GLP-1 receptor agonist that has 90% homology to endogenous human GLP-1.[213] These agents augment early or first-phase insulin response in response to elevated glucose concentrations (i.e., glucose-dependent), moderate glucagon secretion, and decrease hepatic glucose production without impairing the normal glucagon response to hypoglycemia. They slow gastric emptying, thereby reducing the rate at which glucose is absorbed. In addition, they suppress appetite, which may contribute to the prevention of weight gain and the weight loss (1.5–5 kg) observed in patients. A promising action of these agents is their potential to increase β-cell mass and preservation, which has been shown in animal models.

PHARMACOKINETICS

After SC injection, exenatide reaches peak plasma concentrations in 2.1 hours.[214] The injection site (abdomen, thigh, or upper arm) does not significantly alter its kinetics. Both exenatide formulations are eliminated predominantly by glomerular filtration with subsequent proteolytic degradation. The mean terminal half-life of exenatide is 2.4 hours, with levels measurable up to 10 hours, thus allowing for twice-daily dosing. Its metabolism and elimination are dose independent. Extended-release exenatide is released from microspheres over approximately 10 weeks after administration. After discontinuation of therapy, minimal detectable concentrations can be seen in approximately 10 weeks.[215]

Absorption of liraglutide is delayed owing to its self-association in heptameric aggregates within the injection depot that are too large to cross the capillary membranes.[216] On disassociation of the heptamers at the absorption site, liraglutide is absorbed. This delayed absorption is the primary reason for its prolonged action. Liraglutide is highly protein bound (>98%), with a half-life of 13 hours, allowing for once-daily dosing.[211,216] Metabolism of liraglutide occurs endogenously in a manner similar to large proteins and there is no specific organ as its route of elimination.[211,216]

Albiglutide administered SC resulted in maximum concentrations in 3 to 5 days. Steady state is achieved after 4 to 5 weeks of administration. Metabolism to small peptides and amino acids occurs through a metabolic pathway involving proteolytic enzymes in the vascular endothelium. The elimination half-life is approximately 5 days, which allows for once-weekly administration.[212]

Dulaglutide achieves maximum plasma concentration in about 48 hours, and steady state occurs between 2 to 4 weeks with once-weekly administration. There is no statistically significant difference of exposure to dulaglutide between the site of administration in the abdomen, upper arm, or thigh. Metabolism occurs through general protein catabolism pathways into its component amino acids. The elimination half-life is approximately 5 days.[213]

ADVERSE EFFECTS

GI side effects are common and dose-dependent, particularly nausea, vomiting, and diarrhea. Rates vary between agents with albiglutide appearing to have the lowest rates in placebo-controlled trials.[212] These side effects may be lessened by starting patients on lower doses for daily injections, ensuring correct timing and administration of the drug, and titrating the dose slowly. Other reported side effects have included decreased appetite and injection site reactions. Hypoglycemic risk can be increased in patients who are also taking an oral insulin secretagogue (e.g., sulfonylurea) or insulin.[211–215]

These agents have been rarely related to hypersensitivity reactions, acute pancreatitis, and reduced renal function. Patients should be educated about symptoms of acute pancreatitis, including severe abdominal pain accompanied by vomiting, and instructed to report to their practitioner immediately. Patients in whom acute pancreatitis is confirmed with no other probable cause should not be rechallenged with GLP-1 agonists.[211–215]

The development of antibodies against these agents is well established. In general, the presence of antibodies does not appear to significantly affect the A1C reduction seen with GLP-1 agonists, although some patients with high antibody titers may experience reduced efficacy.[211–215,217] Patients who demonstrate adherence to therapy, yet experience no change or worsening in glycemic control, should discontinue therapy and be switched to alternative agents.

CONTRAINDICATIONS AND PRECAUTIONS

GLP-1 agonists are contraindicated in patients with known hypersensitivity. They should not be used in patients with a history of pancreatitis.[211–215] They are not recommended for use in patients with severe GI disease. Exenatide should not be used in severe renal impairment (CrCl <30 mL/minute) or end-stage renal failure, or in those requiring hemodialysis.[215,218] Dulaglutide and albiglutide have limited clinical experience in patients with end-stage renal disease and should be used with caution in these patients. If these patients experience GI adverse effects, renal function should be closely monitored.[212,213]

GLP-1 agonists are contraindicated in patients with a personal or family history of medullary thyroid carcinoma (MTC) or in patients with multiple endocrine neoplasia syndrome type 2 (MEN 2) due to risks in rodents. A causal relationship in humans has not been established.[211–215] Currently, the FDA has required black box warnings on each of the GLP-1 agonists for MTC, MEN 2, and thyroid cancer as well as a REMS program for each medication.

DRUG INTERACTIONS

GLP-1 agonists may increase the risk for hypoglycemia when used with sulfonylureas or insulin. Because of their mechanism of action, they may reduce the rate and extent of absorption of orally administered drugs.[211–215] They should therefore be used with caution in patients taking medications that require rapid GI absorption and are dose-dependent on threshold concentrations for efficacy, such as antibiotics and oral contraceptives. The manufacturers of twice-daily exenatide recommend that patients take the affected medications at least 1 hour before exenatide administration.[214] There have been case reports of an increased international normalized ratio, sometimes associated with bleeding, in patients taking exenatide and warfarin. Patients should be closely monitored, with dose adjustments to warfarin therapy made as needed.[214,215]

EFFICACY

In clinical trials, maximal doses of exenatide combined with a sulfonylurea, metformin, a TZD, or sulfonylurea plus metformin therapy for 30 weeks reduced FBG by 5 to 25 mg/dL, 2-hour postprandial BG by 60 to 70 mg/dL, and A1C by 0.8% to 1.0%.[214,215] Exenatide use for 80 weeks has been reported to reduce body weight by 4 to 5 kg. In a 24-week trial comparing exenatide with extended-release exenatide, the extended-release formulation resulted in a reduction in A1C of 1.6%

and a reduction in FBG of 25 mg/dL.[214,215] Clinical trials with liraglutide monotherapy demonstrate decreases in FBG of 15 to 26 mg/dL and A1C of 0.8% to 1.1%, and weight loss of 2.1 to 2.5 kg.[214] When used as combination therapy, additional A1C lowering of 1% to 1.5% can be expected.[219–221]

Albiglutide as monotherapy in a 52-week trial resulted in A1C reduction of 0.7% to 0.9% and reduction in FBG of 16 to 25 mg/dL. When used in combination therapy, albiglutide reduced A1C by 0.6% to 0.8% and reduced FBG by 18 to 23 mg/dL.[212] Dulaglutide monotherapy resulted in a decrease in A1C of 0.7% to 0.8% and a reduction of FBG of 26 to 29 mg/dL, as well as weight loss of 1.4 to 2.3 kg. When dulaglutide is used in combination therapy, it results in an A1C reduction of 0.8% to 1.5%, a reduction in FBG of 16 to 41 mg/dL, and a weight loss of 0.2 to 2.7 kg.[213]

DOSAGE AND CLINICAL USE

Exenatide (not the extended-release formulation) is approved for use as monotherapy, whereas the other GLP-1 agonists are not recommended as monotherapy per the manufacturers.[211–215] GLP-1 agonists are indicated as add-on agents in patients with Type 2 diabetes who have been unable to reach target goals on monotherapy with metformin or in combination therapy. Although not indicated for weight loss, these agents may be helpful in patients with Type 2 diabetes who are obese and struggling with obesity. Albiglutide and exenatide have been studied in patients with Type 2 diabetes already on insulin glargine; albiglutide lowered the A1C by 0.8%, whereas exenatide lowered the A1C by 1.7% and patients required lower doses of insulin glargine compared with the placebo group.[212,214]

The starting dose of exenatide is 5 mcg injected SC into the abdomen, thigh, or arm twice daily within 60 minutes before morning and evening meals. Patients who experience severe GI side effects may try injecting just before meals initially and then move from 30 to 60 minutes before meals. If a patient tolerates the 5-mcg dose, then it can be titrated after 1 month of therapy to the maximal dose of 10 mcg SC twice daily. The dose of extended-release exenatide is 2 mg given SC once weekly without regard to meals at any time of the day. The starting dose of liraglutide is 0.6 mg injected SC into the abdomen, thigh, or arm once daily for 1 week, and then it may be increased to 1.2 mg SC daily. If the A1C goal is not achieved with a 1.2-mg dose, the dose can be further increased to 1.8 mg daily. The starting dose of albiglutide is 30 mg injected SC into the abdomen, thigh, or upper arm once weekly without regard to meals at any time of the day. The dose can be increased to 50 mg once weekly in patients who have not achieved adequate glycemic control. The starting dose of dulaglutide is 0.75 mg injected SC into the abdomen, thigh, or upper arm once weekly given at any time of the day and may be increased to 1.5 mg once weekly if adequate glycemic control is not achieved.[211–215]

When any of these agents are added to the treatment regimen of a patient who is also taking a sulfonylurea or glinide, the insulin secretagogue dose may need to be lowered (by about half) to reduce the risk of hypoglycemia. If used in combination with basal insulin, the insulin dose may need to be decreased.[211–215]

Dipeptidyl Peptidase-4 Inhibitors

Currently, four DPP-4 inhibitors are available in the United States: sitagliptin, saxagliptin, linagliptin, and alogliptin.[218,222–224]

MECHANISM OF ACTION

The DPP-4 inhibitors inhibit the degradation of GIP and GLP-1 on entering the GI vasculature, thus increasing the effects of these endogenous incretins on first-phase insulin secretion and glucagon inhibition.[225] They are all competitive inhibitors of DPP-4. Sitagliptin, at a 100-mg dose, reduces DPP-4 activity by 80% for up to 24 hours,[222] whereas saxagliptin, at a 2.5-mg dose, reduces DPP-4 activity by 50% for up to 24 hours.[223] Alogliptin, at a dose of at least 25 mg, has been shown to reduce DPP-4 activity by more than 80% at a dose of at least 25 mg for at least 24 hours.[224] Linagliptin, at the standard dose of 5 mg, has been shown to reduce DPP-4 activity by more than 80% for up to 24 hours.[218] In contrast to GLP agonists, which increase GLP-1 levels by 6- to 10-fold,[226] these agents only modestly increase GLP-1 levels (2- to 3-fold), but also increase GIP levels. As a result, DPP-4 inhibitors have minimal-to-no effect on satiety and delaying gastric emptying.

PHARMACOKINETICS

Sitagliptin is rapidly absorbed, with an absolute bioavailability of 87%.[222] Absorption is unaffected by food. Peak plasma concentrations occur in 1 to 4 hours, and its terminal half-life is 12.4 hours. Only

---

38% of sitagliptin is plasma protein bound. Eighty-seven percent of the parent drug is excreted unchanged in the urine, primarily by active renal tubular secretion, and may involve P-glycoprotein and human organic anion transporter-3. Metabolism by CYP 3A4, and to a much lesser extent, CYP2C8, plays a minimal role in the excretion of metabolites in the feces.[227]

Saxagliptin is well absorbed with a bioavailability estimated to be 75%.[223] Although food increases absorption by 27%, it can be administered with or without food. Peak plasma concentrations occur at 2 hours for saxagliptin and 4 hours for the active metabolite. Saxagliptin is metabolized by CYP 3A4/5 to a major metabolite that is one-half as potent.[228] Protein binding of saxagliptin and its active metabolite is negligible. The mean plasma terminal half-lives of saxagliptin and its active metabolite are 2.5 and 3.1 hours, respectively. Saxagliptin is excreted primarily by the kidneys, with 25% excreted unchanged in the urine, and 36% of the active metabolite found in urine. Approximately 22% of drug and metabolite are excreted in feces.[227]

Linagliptin is well absorbed and has a bioavailability of 30%. A high-fat meal can decrease the absorption by 15%; however, this is not clinically significant. Therefore, linagliptin may be administered with or without food. Peak plasma concentrations occur at approximately 1.5 hours after a dose of 5 mg. Linagliptin has a long terminal half-life (>100 hours) due to biphasic decline in plasma concentrations, which is related to the binding of DPP-4. Approximately 90% of linagliptin is excreted unchanged in the urine, and a small percentage is metabolized to an inactive metabolite.[218]

Alogliptin is well absorbed and has a bioavailability of 100%. A high-fat meal results in no significant change in absorption; therefore, it may be administered with or without food. Alogliptin is 20% plasma protein bound, with 60% to 71% of the dose excreted unchanged in urine and 13% excreted in the feces. Limited metabolism occurs via CYP2D6 and CYP3A4. The terminal half-life of alogliptin is approximately 21 hours after the administration of a 25-mg dose.[224]

ADVERSE EFFECTS

Because these agents differ significantly in chemical structure from one another, some adverse events may be unique to the individual agent and may not be indicative of a class wide effect.[225] The most commonly reported side effects with sitagliptin and alogliptin include nasopharyngitis, upper respiratory tract infection, hypoglycemia, and headache.[222,224] Saxagliptin can cause these same adverse effects, as well as urinary tract infection, whereas linagliptin adverse effects can include hypoglycemia, nasopharyngitis, diarrhea, and cough.[218,223] It is possible that DPP-4 inhibitors may have an effect on the immune system, because lymphocytes express DPP-4. These medications have been suggested to increase risk for pancreatitis; however, studies have shown this risk to be low.[229] Additional clinical experience and postmarketing studies are needed to clearly establish the long-term safety of these agents.

CONTRAINDICATIONS AND PRECAUTIONS

All DPP-4 inhibitors should be avoided in patients with a history of serious hypersensitivity reaction to the drug.

DRUG INTERACTIONS

Sitagliptin is not significantly protein bound.[222] It also does not inhibit CYP isoenzymes or induce CYP 3A4; therefore, it is not expected to interact with other drugs that are metabolized by these pathways. Patients taking digoxin, a substrate of P-glycoprotein-like sitagliptin, should be monitored for any signs or symptoms of digoxin toxicity, because a slight increase in the AUC (11%) and C_{max} (18%) has been observed.[222,226]

Saxagliptin does have significant drug interactions because it is metabolized by CYP 3A4/5.[223] Therefore, if used with strong inhibitors of these enzymes (e.g., ketoconazole, itraconazole, clarithromycin, telithromycin, protease inhibitors such as indinavir), the dose of saxagliptin is reduced to 2.5 mg daily.

Linagliptin is a weak-to-moderate inhibitor of CYP3A4 and a P-glycoprotein substrate and inhibits P-glycoprotein-mediated transport of digoxin at high concentrations.[218] Medications that are strong inducers of CYP3A4 or P-glycoprotein, such as rifampin, decrease linagliptin to levels that are subtherapeutic and ineffective; therefore, if treatment with those medications is necessary, an alternative to linagliptin should be used.

Alogliptin is not significantly protein bound, and metabolism through the cytochrome P450 pathway is negligible; therefore, there are no significant drug interactions with alogliptin.[224]

EFFICACY

In monotherapy clinical trials versus placebo, sitagliptin lowers fasting glucose by 12 mg/dL and A1C by 0.5% to 0.6% compared with baseline (0.6%–0.8% compared with placebo)[222]; saxagliptin is comparable, with A1C lowering by 0.5% (0.6% vs. placebo) and FPG by 15 mg/dL.[223] In addition, both agents reduce 2-hour postprandial glucose by approximately 45 mg/dL.[222,223,226] When used as add-on combination therapy, A1C lowering is greater (0.7%–0.9%). Linagliptin, as monotherapy in clinical trials versus placebo, decreased fasting glucose by 13 mg/dL from baseline and decreased A1C by 0.4%.[218] Alogliptin, as monotherapy in clinical trials versus placebo, decreased fasting glucose by 16 mg/dL and A1C by 0.6%.[224] Unlike the GLP-1 mimetics and analogs, DPP-4 inhibitors do not significantly affect body weight, appetite, or satiety, and are considered weight neutral.[226] As is the case for the GLP-1 mimetics and analogs, further studies are needed to more clearly determine the effects of DDP-4 inhibitors on long-term preservation of β-cell function.

DOSAGE AND CLINICAL USE

DPP-4 inhibitors are mainly used as add-on therapy in combination with other agents. However, all are approved for use as monotherapy. Sitagliptin may be initiated at 100 mg taken once daily with or without food.[222] Renal function should be assessed before initiation of this agent. In patients with moderate renal insufficiency (CrCl 30–50 mL/minute), the dose for sitagliptin should be reduced to 50 mg once daily, and in severe renal insufficiency (CrCl <30 mL/minute) or for those in end-stage renal failure requiring dialysis, the sitagliptin dose is 25 mg once daily. Sitagliptin may be administered without regard to the timing of hemodialysis. Only sitagliptin should be used in patients on peritoneal dialysis.

Saxagliptin is dosed at 2.5 to 5 mg once daily with or without food.[223] Renal function should be assessed before initiation of this agent. In patients with moderate or severe renal impairment or end-stage renal disease with a CrCl < 50 mL/minute, the recommended dose is 2.5 mg daily. If patients are taking strong CYP3A4/5 inhibitors, the dose of saxagliptin should be 2.5 mg daily. In hemodialysis patients, the dose is 2.5 mg daily to be administered after hemodialysis.

Linagliptin is dosed at 5 mg once daily with or without food. No dose adjustment is necessary for patients with renal impairment; however, patients with a CrCl <30 mL/minute may be more prone to hypoglycemia; therefore, dosing adjustments of concomitant antidiabetic medications and frequent monitoring may be necessary.[218]

Alogliptin is dosed at 25 mg once daily with or without food. Renal function should be assessed prior to initiation of this medication. In patients with moderate renal impairment with a CrCl of 30 to 60 mL/minute, the recommended dose is 12.5 mg once daily. In patients with severe renal impairment (CrCl <30 mL/minute) or end-stage renal disease, the dose is 6.25 mg once daily. Patients on hemodialysis should be given 6.25 mg once daily and it may be administered without regard to the timing of dialysis.[224]

When any of these agents are added to a patient also on a sulfonylurea or glinide, the insulin secretagogue dose may need to be lowered (by about half) to reduce the risk of hypoglycemia. Similarly, when sitagliptin is added to a patient already on insulin therapy, the dose(s) of insulin may need to be lowered initially and then readjusted depending on the response to sitagliptin.

Amylin Receptor Agonists (Amylinomimetics)

MECHANISM OF ACTION

Amylin is a hormone found in the β-cells where it is comanufactured, stored, and released with insulin in response to food intake.[230] Its actions seem to be centrally mediated and include slowing gastric emptying, suppressing glucagon secretion, and modulating the regulation of appetite. Amylin is absent in patients with Type 1 diabetes. In patients with Type 2 diabetes, its concentrations are altered to mirror those of insulin at different points in the progression of the disease. Pramlintide, a synthetic amylin analog, is available in the United States for the adjunctive treatment of both Type 1 and Type 2 diabetes who use mealtime insulin.

PHARMACOKINETICS

The absolute bioavailability of SC injected pramlintide is 30% to 40%.[231] Subcutaneous injection into the abdomen and thigh allows for more predictable absorption and distribution than when administered into the arm. Approximately 40%

of the drug is unbound in plasma. The half-life is about 48 minutes, and time to maximum concentration is approximately 20 minutes. Pramlintide is metabolized by the kidneys to an active metabolite with a half-life similar to the parent drug.

ADVERSE EFFECTS

GI symptoms—including mild-to-moderate nausea (28%–48%), vomiting (8%–11%), and anorexia (9%–17%)—are the most frequently reported adverse reactions associated with therapy.[231] GI symptoms are usually transient, subsiding after 4 to 8 weeks of treatment or with dose reduction and slow dose escalation. Hypoglycemia can occur in up to 16.8% of Type 1 diabetes patients receiving pramlintide and insulin therapy, and in 8.2% of Type 2 diabetes patients receiving pramlintide and insulin.

CONTRAINDICATIONS AND PRECAUTIONS

Pramlintide is contraindicated in patients with known cresol hypersensitivity, hypoglycemic unawareness, and gastroparesis.[231] Severe hypoglycemia can occur when it is used in combination with insulin and medications that can slow gastric emptying. Drugs that can alter glucose metabolism when administered with pramlintide, and therefore cause hypoglycemia, include oral antidiabetics, fibrates, fluoxetine, salicylates, and ACE inhibitors, and should be used with caution if administered concomitantly. Pramlintide has a black box warning for severe hypoglycemia, which can occur within 3 hours following an injection of pramlintide. Caution individuals while driving, those who operate heavy machinery, and those who engage in other high-risk activities due to potential serious injuries that may result during a hypoglycemic episode.

DRUG INTERACTIONS

As noted, severe hypoglycemia can occur in patients who are concurrently taking an oral hypoglycemic agent (e.g., sulfonylurea) or insulin (see Dosage and Clinical Use section).[231] Because pramlintide can delay the absorption of medications that are administered concomitantly, medications that require rapid onset for effectiveness, such as antibiotics, oral contraceptives, and analgesics, should be administered at least 2 hours after or 1 hour prior to the pramlintide injection.

EFFICACY

In clinical studies of patients with Type 2 diabetes with doses up to 150 mcg/day for 52 weeks, pramlintide combined with insulin decreased A1C by 0.3% and weight by 2.57 kg.[231] Clinical studies of patients with Type 1 diabetes taking insulin in combination with pramlintide or placebo demonstrated A1C reductions of 0.2% to 0.4% and weight loss of 0.4 to 1.3 kg.[56]

DOSAGE AND CLINICAL USE

In clinical practice, pramlintide is considered an add-on agent primarily for patients with Type 1 diabetes who have failed to achieve target BG goals on insulin therapy alone. Its practical use is more limited to obese patients with Type 2 diabetes who have failed to achieve target BG levels with a regimen that includes a sulfonylurea or insulin. Pramlintide is available in a pen device (SymlinPen). It cannot be mixed with any type of insulin. The pens (60 pen-injector for 15-, 30-, 45-, or 60-mcg doses and 120 pen-injector for 60- and 120-mcg doses) in use may be stored at room temperature (86°F or 30°C) for up to 30 days.[231]

For patients with Type 1 diabetes, the initial dose is 15 mcg, and for patients with Type 2 diabetes, the initial dose is 60 mcg. Pramlintide is injected SC into the abdomen or thigh immediately before every major meal. A major meal is one that contains 30 g or more of carbohydrate or 250 kcal or more. If a meal is skipped, the pramlintide dose should be skipped. When initiating pramlintide therapy, the dose of premeal insulins must be reduced by at least 50%. Patients should be closely followed and instructed to intensively monitor and record BG (fasting, preprandial, and postprandial) levels and any hypoglycemic episodes until control has stabilized. Pramlintide is titrated based on achieving optimal glucose control with minimal side effects (e.g., nausea). The dose can be increased when no clinically significant nausea has occurred for 3 to 7 days. For patients with Type 1 diabetes, doses may be increased in 15-mcg increments up to a maximum meal dose of 60 mcg. For patients with Type 2 diabetes, the dose may be increased to 120 mcg before every major meal.[231]

Sodium–Glucose Transporter 2 (SGLT2) Inhibitors

SGLT2 inhibitors reduce BG by decreasing tubular reabsorption of glucose in the kidney, thereby increasing the excretion of urinary glucose.[231] These agents are highly selective, reversible inhibitors of SGLT2. Currently, there are three agents in this class: canagliflozin, dapagliflozin, and empagliflozin, which are available as individual agents or in combination with other antidiabetic agents.[232–234] Because their mechanism of action is independent of insulin resistance or β-cell function, these medications can be used in combination with all antidiabetic agent classes, including insulin, for the treatment of Type 2 DM in addition to diet and exercise. These agents have added benefits of weight loss, increase in HDL, and decrease in blood pressure; however, genital and urinary infections may be an adverse effect of these agents.[235]

PHARMACOKINETICS

Canagliflozin has a bioavailability of 65%, and peak plasma concentrations occur within 1 to 2 hours after the dose is administered.[232] There was no effect on absorption when administered with a high-fat meal; therefore, canagliflozin may be administered with or without food. Canagliflozin is 99% protein bound, primarily to albumin. This agent is metabolized primarily by glucuronidation

---

by UGT1A9 and UGT2B4 to two inactive metabolites. Approximately 7% is metabolized by CYP3A4. Approximately 33% of a dose is excreted in the urine as metabolites and <1% is excreted as unchanged canagliflozin in the urine. The terminal half-life is 10.6 hours for a 100-mg dose and 13.1 hours for a 300-mg dose.

Dapagliflozin has a bioavailability of 78% after the administration of a 10-mg dose.[233] The maximal serum concentration (C_{max}) occurs at approximately 2 hours under fasting state. Taking dapagliflozin with a high-fat meal decreases the C_{max} by up to 50%; however, this change is not clinically significant. Therefore, it may be administered with or without food. Dapagliflozin is approximately 91% protein bound and is metabolized primarily by the UGT1A9 pathway and to a small extent by CYP 3A4 to yield inactive metabolites. This agent and the inactive metabolites are excreted 75% in the urine and 21% in the feces, with 15% being excreted as unchanged drug. The terminal half-life is approximately 12.9 hours following a single-dose administration.

Empagliflozin reached peak plasma concentrations at 1.5 hours postoral administration.[234] Plasma concentrations then declined in a biphasic manner with a rapid distribution phase and a slower terminal phase. The C_{max} decreased by 37% after administration with a high-fat meal; however, this was determined to be clinically insignificant. Therefore, empagliflozin may be administered with or without food. Empagliflozin is 86.2% bound to plasma proteins, and the agent is primarily metabolized by glucuronidation by UGT3B7, UGT1A3, UGT1A8, and UGT1A9. No major metabolites were detected in plasma. Approximately 41.2% of the drug was eliminated in feces (unchanged parent drug), whereas 54.4% was eliminated in urine (half is unchanged parent drug). The terminal half-life is approximately 12.4 hours.

ADVERSE EFFECTS

Canagliflozin commonly reported adverse effects include female genital mycotic infections, increased urination, and urinary tract infections.[232] The most common adverse effects associated with dapagliflozin include nasopharyngitis, urinary tract infections, and female genital mycotic infections.[233] The most common adverse effects associated with empagliflozin include female genital mycotic infections and urinary tract infections.[234]

CONTRAINDICATIONS AND PRECAUTIONS

All SGLT2 agents are contraindicated in patients with hypersensitivity reactions to the agents and in patients with severe renal impairment, ESRD, and dialysis.[233–234]

Based on the mechanism of action of these agents, they would be ineffective in patients with severe renal impairment and would place these patients at increased risk for renal adverse effects. Renal function should be assessed prior to the initiation of these agents and periodically during treatment. Blood pressure should be assessed in patients prior to initiation with these agents and hypovolemia should be corrected due to the potential of these agents to lower blood pressure, especially in patients already taking antihypertensive medications. Hypoglycemia may occur when SGLT2 agents are used in combination with insulin and secretagogues; therefore, the doses of the concomitant agents may need to be decreased. Renal function may be impaired with use of these agents; therefore, renal function monitoring should occur during therapy. Serum concentrations of LDL may be increased with SGLT2 therapy, which may require medication therapy, and serum LDL concentrations should be monitored. In clinical trials, dapagliflozin has shown an increase in bladder cancer cases as compared to placebo; therefore, patients with previous history of bladder cancer should not take dapagliflozin.[235]

In May 2015, the FDA released a Drug Safety Communication warning that SGLT2 agents may cause ketoacidosis and patients should be warned to seek medical attention if they experience signs and symptoms of ketoacidosis including confusion, fatigue, difficulty breathing, abdominal pain, nausea, or vomiting.[236] The cases were not typical of DKA cases, because blood sugars were not highly elevated. In some of the cases, DKA may have been triggered by major illness. The FDA will monitor the safety of these agents and determine whether prescribing information changes are warranted.

DRUG INTERACTIONS

Canagliflozin weakly inhibits CYP2B6, CYP2C8, CYP2C9, and CYP3A4, is a weak inhibitor of P-gp, and is a substrate of drug transporters P-gp and MRP2.[232] Rifampin decreases the efficacy of canagliflozin; therefore, the dose of canagliflozin may need to be increased. When administered concomitantly with digoxin, there was an increase in the AUC (20%) and C_{max} (36%) of digoxin; therefore, digoxin should be monitored appropriately.

Dapagliflozin does not inhibit CYP enzymes and is a weak substrate of the P-glycoprotein (P-gp) active transporter. The dapagliflozin metabolite is a substrate for the OAT3 active transporter; however, it did not inhibit P-gp, OCT2, OAT1, or OAT3 active transporters with any clinical significance. Therefore, dapagliflozin is unlikely to affect the pharmacokinetics of concurrently administered medications that are substrates of these enzymes. Coadministration of dapagliflozin with rifampin, a nonselective inducer of UGT1A9, may cause a decrease in dapagliflozin serum concentrations, which may lead to a decrease in dapagliflozin efficacy.[233]

Empagliflozin does not induce or inhibit CYP450 enzymes or UGT1A1; therefore, it is not expected to have interactions with concomitantly administered medications that are substrates of the CYP450 pathway or UGT1A1.[234]

EFFICACY

Canagliflozin monotherapy versus placebo decreased A1C by 0.77% to 1.03%, decreased FPG by 27 to 35 mg/dL, and decreased body weight by 2.8% to 3.9%.[232] In a clinical trial comparing dapagliflozin monotherapy to placebo, A1C was decreased by 0.8% to 0.9% and FPG was decreased by 24.1 to 28.8 mg/dL.[233] Empagliflozin monotherapy, in a clinical trial compared to placebo, decreased A1C by 0.7% to 0.8%, decreased FPG by 19 to 25 mg/dL, and decreased body weight by 2.8 to 3.2%.[234]

DOSAGE AND CLINICAL USE

The SGLT2 agents are indicated for use in patients with Type 2 DM as an adjunct to diet and exercise as monotherapy or concomitantly with other antidiabetic agents. The initial dose of canagliflozin is 100 mg once daily taken before the first meal of the day and can be increased to 300 mg once daily in patients who need additional glycemic control and have an eGFR > 60ml/min/1.73 m^2.[237] In patients with an eGFR of 45 to 60 mL/minute/1.73 m^2, the dose is limited to 100 mg once daily and should be discontinued in patients with an eGFR <45 mL/minute/1.73 m^2.[232] Dapagliflozin should be initiated at a dose of 5 mg once daily in the morning, with or without food, and the dose may be increased in patients who need additional glycemic control.[233] Monitor renal function prior to initiation and do not use in patients with an eGFR <60 mL/minute/1.73 m^2. Empagliflozin should be initiated at a dose of 10 mg once daily in the morning, with or without food, and may be increased to 25 mg once daily.[238] Do not initiate empagliflozin therapy in patients with an eGFR <45 mL/minute/1.73 m^2 and discontinue therapy if eGFR persistently falls below 45 mL/minute/1.73 m^2.[234]

Other Agents

COLESEVELAM

In January 2008, the FDA approved a new indication for colesevelam (Welchol), a bile acid sequestrant, to be used as add-on therapy in Type 2 diabetes as an adjunct to diet and exercise.[239]

The mechanism by which colesevelam reduces glucose is not known. It is a hydrophilic, water-insoluble polymer that is not absorbed. Therefore, its distribution is limited to the GI tract.[239–242] The primary side effects of colesevelam are GI (constipation, nausea, and dyspepsia). The following are contraindications for use of colesevelam:

- Patients with triglyceride levels of more than 500 mg/dL

- Patients with a history of bowel obstruction
- Patients with a history of pancreatitis caused by hypertriglyceridemia
- Patients with of Type 1 diabetes or for the treatment of DKA

Because of its constipating effects, it should not be used in patients with gastroparesis, other GI motility disorders, or in those who have had major GI tract surgery and may be at risk for bowel obstruction. The tablets are large and can cause dysphagia or esophageal obstruction; therefore, it should be used with caution in patients with dysphagia or swallowing disorders. It should be used with caution in patients with triglycerides in excess of 300 mg/dL because bile acid sequestrants can cause concentrations of serum triglycerides to increase.[240–242]

Drug interactions are an important consideration for colesevelam because it reduces GI absorption of some drugs. Drugs with a known interaction with colesevelam (e.g., phenytoin, warfarin, levothyroxine, oral contraceptives) should be administered at least 4 hours before colesevelam. The bioavailability of glimepiride, glyburide, and glipizide may be affected by concomitant administration of colesevelam; therefore, these medications should be administered 4 hours prior to colesevelam.[239]

A1C reductions associated with colesevelam are 0.3% to 0.4% compared with baseline (0.5% vs. placebo). Colesevelam also reduces LDL-C by 12% to 16% when used in combination with metformin or a sulfonylurea respectively.[243] Bile acid sequestrants can increase triglycerides by 5% to 22% in patients with Type 2 diabetes, depending on which antidiabetic medications are given concomitantly.[239–242] Colesevelam is approved for use as combination therapy with metformin, a sulfonylurea, and insulin.[239] It has not been studied as monotherapy or in combination with DPP-4 inhibitors. It can provide an added benefit in patients with dyslipidemia. The dose is six (625 mg) tablets once daily or three tablets twice daily taken with a meal and liquid. Alternatively, a 3.75-g packet (powder for oral suspension) once daily or 1.875-g packet twice daily may be used by dissolving each dose in 4 to 8 ounces of water, fruit juice, or diet soda, and administering with a meal. Since its approval, its use for treatment of Type 2 diabetes remains quite limited.

BROMOCRIPTINE

Bromocriptine mesylate, an ergot derivative, is a dopamine-2 receptor agonist that is a quick-release formulation.[244] It was FDA-approved in May 2009 for use in Type 2 diabetes. Bromocriptine has been available since 1978 and was once widely used for Parkinson disease. The mechanism by which bromocriptine improves glycemic control is not known. A normal circadian peak in the central dopaminergic tone occurs in the early morning and has been linked to induction of normal insulin sensitivity and glucose metabolism.[237] It is theorized that taking bromocriptine in the morning will increase central dopaminergic tone and reset the normal circadian rhythm to that of leaner people. The recommended dose of bromocriptine in diabetes is initiation with 0.8 mg daily, increasing by one tablet weekly until the maximum tolerated dose of 1.6 to 4.8 mg is reached. Bromocriptine is administered once daily within 2 hours after waking in the morning.[244] It should be taken with food to help reduce GI side effects such as nausea. Its effect on A1C lowering is very mild: As monotherapy, A1C is lowered by 0.1% compared with baseline (0.4% vs. placebo), and as add-on therapy to a sulfonylurea or metformin, A1C is reduced by 0.5%. Common side effects include hypotension, dizziness, syncope, nausea, somnolence, headache, and exacerbation of psychotic disorders. Bromocriptine is contraindicated in patients with known hypersensitivity to ergot-related drugs, patients with syncopal migraine, and women who are nursing.[244] Bromocriptine is highly protein bound, and when given concomitantly with other drugs that are highly protein bound, such as sulfonamides, salicylates, and probenecid, the unbound fraction of these other drugs may increase, altering their risk of adverse effects or their effectiveness. Bromocriptine is metabolized by CYP3A4; therefore, caution should be used when administering concomitant drugs that are CYP3A4 substrates, inducers or inhibitors. Neuroleptic agents with dopamine receptor agonist properties, such as olanzapine, clozapine, and ziprasidone, may reduce the effectiveness of both bromocriptine and the other drugs; therefore, concomitant use is not recommended. Given the minor A1C lowering, bromocriptine quick release has a very limited role as a therapeutic agent.[244]

TREATMENT OF PATIENTS WITH TYPE 2 DIABETES

Clinical Presentation

CASE 53-11

QUESTION 1: L.H. is a 45-year-old, overweight, Mexican American woman with central obesity (height, 5 feet 5 inches; weight, 165 lb; BMI, 27.5 kg/m^2). Three months ago, she was referred to the diabetes clinic when her gynecologist, who had been treating her for recurrent monilial infections, noted glucosuria on routine urinalysis. Subsequently, on two separate occasions, she was found to have an FPG of 150 and 167 mg/dL; an A1C was also checked and it was 8.2%. L.H. denies any symptoms of polyphagia or polyuria, although lately she has been more thirsty than usual. She does complain of lethargy and takes afternoon naps when she can.

L.H.’s other medical problems include hypertension, which is well controlled on lisinopril 20 mg/day, and recurrent monilial infections, which are treated with fluconazole. She has given birth to four children (birth weights, 7, 8.5, 10, and 11 lb) and was told during her last pregnancy that she had “borderline diabetes.” She currently works as a loan officer in a local bank and spends her weekends “catching up on her sleep” and reading. L.H. has been smoking one pack of cigarettes per day for 20 years and drinks an occasional glass of wine. She drinks at least two regular sodas daily and has a “large” glass of orange juice every morning. Her physical activity consists of routine walking during the day (e.g., to her car). Her family history is significant for a sister, aunt, and grandmother with Type 2 diabetes; all have “weight problems.” L.H.’s mother is alive and well at age 77; her father died of a heart attack at age 47.

On presentation, fasting laboratory assessment reveals glucose of 147 mg/dL, triglycerides of 400 mg/dL, and an A1C of 8.3% (normal, 4%–6%). All other values (including the complete blood count, electrolytes, LFTs, and renal function tests) are within normal limits. L.H. is given the diagnosis of Type 2 diabetes. What features in L.H.'s history and physical examination are consistent with this diagnosis?

The features of L.H.'s history that are consistent with Type 2 diabetes include an FPG concentration of 126 mg/dL or higher on more than one occasion, a A1C of 6.5% or more, high BMI with central obesity, age older than 40, physical inactivity, family history of diabetes, and Mexican American descent. L.H. also has delivered large babies, which suggests that she may have had undiagnosed gestational diabetes, a condition that places women

---

at high risk for subsequently developing Type 2 diabetes. Diagnosis on routine examination and mild signs and symptoms of hyperglycemia (including increased thirst and lethargy), recurrent monilial infections, hypertriglyceridemia, and indications of CVD (hypertension) also are typical in patients with Type 2 diabetes (see Type 2 Diabetes section and Table 53-1).

Treatment Goals

CASE 53-11, QUESTION 2: What should the goals of therapy be for L.H. and other patients with Type 2 diabetes? Which biochemical indices should be monitored?

The beginning of this chapter discussed general goals of therapy for all people with diabetes, which include eliminating acute symptoms of hyperglycemia, avoiding hypoglycemia, reducing cardiovascular risk factors, and preventing or slowing the progression of both microvascular and macrovascular diabetic complications. The ADA recommends that otherwise healthy patients with Type 2 diabetes strive to achieve the same biochemical goals as those recommended for people with Type 1 diabetes (Tables 53-4 and 53-5).[7] When determining treatment goals for L.H. and others with Type 2 diabetes, the same individual characteristics should be considered as for Type 1 diabetes, such as the patient's capacity to understand and carry out the treatment regimen and the patient's risk for severe hypoglycemia. Given the data from the ACCORD, ADVANCE, and VADT trials, patients with Type 2 diabetes and CVD or multiple CVD risk factors should be carefully assessed when determining their glycemic goals. For example, less aggressive A1C goals should be considered for patients with advanced age (and short life expectancy), longer duration of diabetes (more than 10 years), advanced microvascular complications, or comorbid conditions such as significant cerebrovascular or coronary artery disease because of the serious consequences related to hypoglycemia. Therefore, glycemic goals for patients with Type 2 diabetes must be individualized. Emphasis should be placed on assessment of all cardiovascular risk factors, including hypertension, tobacco use, dyslipidemia, and family history.

As presented earlier in the Relationship of Glycemic Control to Microvascular and Macrovascular Disease section, the UKPDS was a landmark study in patients with Type 2 diabetes that conclusively demonstrated that improved BG control reduces the risk of developing retinopathy, nephropathy, and, potentially, neuropathy.[35,44,238] The 10-year follow-up study demonstrated that these outcomes persist even though the conventional group achieved similar glycemic control with time; an overall relative risk reduction in microvascular complications (24%) in the sulfonylurea- or insulin-treated group compared with patients who initially received conventional therapy was seen.[33] The exciting finding was that reductions in macrovascular complications emerged with time, with significant reductions in MI (15%) and death of any cause (13%) in patients initially intensively treated with sulfonylurea or insulin. Metformin appeared to be of particular benefit, with even greater reductions in MI and death of any cause (33% and 27%, respectively).

An additional finding of the UKPDS was that aggressive control of BP also significantly reduced microvascular complications, strokes, diabetes-related deaths, HF, and vision loss; during the 10-year follow-up study, these benefits diminished with time as the BP difference between the two groups was lost (i.e., BP increased in the tight control group and decreased in the conventional group).[245–247] These findings stress the importance of maintaining good BP control to reduce the risk of long-term complications.

Because L.H. is relatively young and has no symptoms of microvascular disease or neuropathy, every effort should be made to normalize her glucose concentrations to prevent these complications. Furthermore, a lipid panel should be ordered, and steps should be taken to achieve normal LDL-C, HDL-C, and triglyceride levels. Often, triglyceride levels improve as BG concentrations decline and the metabolic response to insulin improves. (Management of dyslipidemia is addressed more fully later in this chapter.)

Biochemical indices that should be followed to monitor L.H.'s response to therapy include fasting, postprandial, and preprandial BG concentrations, A1C values, and fasting triglyceride levels, as well as LDL-C and HDL-C concentrations. Based on ADA guidelines initial metabolic goals for L.H. should be an A1C value of less than 7%, an FPG of 80 to 130 mg/dL and postprandial glucose concentrations less than 180 mg/dL.[7]

Treatment

LIFESTYLE INTERVENTIONS AND INITIAL THERAPY WITH METFORMIN

CASE 53-11, QUESTION 3: How should L.H. be managed initially?

Initial therapy of Type 2 diabetes is aimed at lifestyle changes that will minimize insulin resistance and risk for CVD. In L.H.'s case and in the case of other overweight (BMI, 25.0–29.9 kg/m^2) or obese (BMI ≥30.0 kg/m^2) Type 2 diabetes individuals, this includes a lower-calorie, low-fat, low-cholesterol diet; regular exercise; smoking cessation (see Chapter 91, Tobacco Use and Dependence); and aggressive management of dyslipidemia and hypertension. Because central obesity is associated with increased insulin resistance, L.H. should be strongly encouraged to decrease her caloric intake, start exercising, and lose weight. Simple changes in her diet (such as cutting out juice and regular soda) and physical activity level can have a large impact on her glucose control. SMBG monitoring should be encouraged, and education that addresses the serious nature of diabetes mellitus and its long-term consequences also should begin. This is discussed in the previous sections, Medical Nutrition Therapy and Physical Activity, under Treatment (See also Table 53-14).

Initial Pharmacologic Therapy with Metformin

The ADA recommends that most patients diagnosed with Type 2 diabetes begin therapy with lifestyle modifications, including those mentioned above. In addition, most patients should begin monotherapy with metformin upon diagnosis. If metformin is contraindicated or poorly tolerated, agent approved for monotherapy may be used.[7] The selection of alternative agents will be discussed later in this chapter.

Although the UKPDS demonstrated that intensive therapy with sulfonylureas, metformin, and insulin reduces glucose with equal effectiveness (TZDs were not studied), metformin is favored as a first-choice agent in Type 2 diabetes, particularly in overweight patients. This is because metformin lowers BG by decreasing hepatic glucose output and insulin resistance (indirectly) without causing weight gain or hypoglycemia. Metformin also has beneficial effects on plasma lipid concentrations as well due to a reduction in LDL as well as fatty acids.[238]

Another reason for metformin being a first choice for initial therapy is not only its proven benefit to reduce risk of microvascular complications, but also macrovascular disease and mortality.[33] Furthermore, in an observational study of patients with Type 2 diabetes, and established coronary artery disease, cerebrovascular disease, or peripheral arterial disease, metformin use was associated with a significant reduction in all-cause mortality (22%) after only 2 years of follow-up.[243] Metformin is also emerging as a therapy that may reduce cancer risk, possibly attributable to its activation

---

of AMPK, which can suppress tumor formation. Data so far have been in animal models and observational studies in humans.[248]

A drawback to immediate-release metformin is that it requires multiple daily dosing and its dose also must be titrated to minimize GI effects. After the dose is established, it is possible to use a long-acting product that can be dosed once daily. Alternatively, extended-release metformin may be initiated at a dose of 500 mg daily and titrated upward as tolerated. Renal function tests should be evaluated before the drug is initiated. L.H. does not have any contraindications (renal or hepatic dysfunction, cardiorespiratory disease, binge alcohol use) to the use of metformin that could predispose her to its most significant side effect, lactic acidosis (see Case 53-16, Question 2). Because L.H. exhibits the typical features of insulin resistance syndrome and has no contraindications for its use, she should be started on metformin. Her A1C goal of less than 7% will require an additional 1.3% lowering in her A1C, which can be achieved with metformin. However, any changes in her lifestyle will further help lower her A1C. L.H. should take metformin 500 mg twice daily with food.

Titrating Metformin Doses

CASE 53-11, QUESTION 4: L.H. is started on metformin 500 mg BID with food and instructed to increase her dosage to 500 mg every morning and 1,000 mg every evening after 1 week. Three days after starting metformin, she phones the clinic complaining of nausea and diarrhea. She admits to taking her doses on an empty stomach. How should L.H.'s symptoms be addressed?

GI disturbances such as diarrhea, bloating, anorexia, abdominal discomfort, nausea, and metallic taste often dissipate with time and can be minimized by initiating metformin in a single 500- or 850-mg dose at breakfast or with the patient's largest meal of the day. Consistently taking metformin with food significantly minimizes the GI side effects. The dosage should be slowly increased (e.g., 500 mg/day every 2 weeks) until the appropriate clinical effect is achieved or the patient is taking the maximal dose (1,000 mg BID or 850 mg TID). Therefore, L.H.'s metformin dose should be reduced to 500 mg daily with her largest meal, and she should be titrated more slowly during a period of several weeks. Metformin is typically dosed 2 to 3 times daily (the long-acting formulation is dosed once daily with dinner). Twice-daily dosing for adherence purposes is preferred if a patient can tolerate a 1,000-mg dose or once daily with the extended-release formulation. If she continues to experience GI symptoms, an alternative approach is to use the extended-release formulation; small studies have demonstrated improved tolerability with the extended-release tablets versus the immediate-release dosage form.[249] A drawback to these tablets is their very large size. Also, patients may complain that metformin has a fishy odor,[250] which seems to be more apparent with certain generic formulations. If this is significant enough to cause a patient to stop taking it, the extended-release formulation can be tried, which may be more tolerable.

Monitoring Metformin Therapy

CASE 53-11, QUESTION 5: How should metformin therapy be monitored in L.H.?

As is standard with other agents, L.H. should be encouraged to perform SMBG (see Case 53-11, Question 6) and have an A1C test performed quarterly until she achieves consistent values less than 7%. Additional evidence of the therapeutic benefits of metformin may include an improved lipid profile and some weight loss. Initially, it is important to monitor GI problems, and although lactic acidosis is unlikely, L.H. should be warned to bring to the attention of her physician any sudden symptoms of shortness of breath, weakness, and malaise. A baseline SCr, LFTs, and complete blood count should be obtained for L.H. and repeated yearly. Metformin can reduce vitamin B_{12} absorption, and it is associated with reductions in vitamin B_{12} levels (19% after 4 years of use in one study) and actual deficiency.[251] Therefore, monitoring of vitamin B_{12} levels every 2 to 3 years should be considered with long-term use.

SELF-MONITORING OF BLOOD GLUCOSE IN TYPE 2 DIABETES

CASE 53-11, QUESTION 6: L.H. is interested in learning how to perform BG testing. What are the advantages and disadvantages of SMBG tests? When and how often should L.H. be instructed to test her BG concentrations?

SMBG is an important self-management tool for patients such as L.H. to assess the efficacy of therapy and guide adjustments in nutrition, exercise, and medications. Disadvantages include cost of testing, inadequate understanding by both healthcare providers and patients regarding the benefits and proper use of SMBG results, patient psychological and minor physical discomfort associated with obtaining a blood sample, and the inconvenience of testing. However, with the current advances in meter technology and proper patient education, most of these potential barriers can be overcome.

The ADA states that SMBG may be a useful guide for patients with Type 2 diabetes treated with MNT or noninsulin therapies, although there is insufficient evidence to determine optimal frequency of testing and demonstrate cost-effectiveness for these patients. Although one meta-analysis of SMBG effects in patients with Type 2 diabetes not on insulin concluded the overall effect on A1C was a 0.4% reduction, others failed to show a benefit.[252,253] SMBG studies in patients with Type 2 diabetes are often limited in that multiple interventions, such as education, diet, and medication adjustments, were used. However, a primary reason studies fail to show a benefit is that patients are not taught what to do with their BG numbers (i.e., how to respond to a low BG reading); the BG values are solely used by the providers to make adjustments to their therapy.[253]

SMBG should be considered for most patients with Type 2 diabetes, particularly those who are learning to adjust their carbohydrate intake and portion sizes and want to measure how well medications and lifestyle changes are working to improve their glucose control. Although not always cost-effective, testing 4 times daily before meals and at bedtime for 1 week is useful, so that the patient can observe his/her glucose profiles. Later, once the desired A1C has been achieved, BG can be tested less frequently. Testing times should vary throughout the day so that fasting as well as postprandial and bedtime values can be assessed. As emphasized by the ADA, intensive patient education regarding testing technique and interpretation are vital to the cost-effective use of this monitoring tool. The patient must learn how to respond to his/her glucose profile and institute lifestyle changes that can have a favorable effect.

Clinical Use of Antidiabetic Agents

CASE 53-11, QUESTION 7: L.H. was quite motivated to improve her glucose control because her grandmother “lost a leg” to diabetes and her aunt is undergoing dialysis because “her kidneys have failed.” She is taking metformin 1,000 mg PO BID and tolerating it reasonably well (she occasionally gets some stomach discomfort, but states she is fine with it). She is proud that she remembers to take the metformin every day as instructed. She met with a dietitian who suggested an 1,800-calorie diet and 45-minute walks 3 times weekly. After 3 months, L.H. lost 6 pounds. L.H. stopped drinking regular sodas and juices, but eats either breads or two large tortillas at each meal. She admits to eating only small amounts of “greens” and vegetables. She has not been able to implement her walks 3 times weekly; more often she only walks once a week. Although her FPG fell to 130 mg/dL, a majority of her postprandial BG levels were more than 180 mg/dL. Her A1C is 7.4%, and fasting triglyceride levels are now 260 mg/dL. How should her therapy be adjusted? What factors should be considered when deciding on the next steps for pharmacologic therapy?

L.H.’s A1C has improved by 0.9%. However, she has not fully instituted lifestyle interventions. Although she has cut out juices and regular sodas, she can still further improve her diet and lower her postprandial BG (to <180 mg/dL) by reducing her carbohydrate intake, switching to whole-grain breads, and increasing her vegetable intake. She also can increase her physical activity to at least 3 times weekly. Although the A1C is not less than 7%, a reasonable approach would be to continue metformin at 1,000 mg PO BID and reinforce lifestyle changes at this point before modifying her pharmacologic therapy.

The amount of A1C lowering in response to adding an antidiabetic agent appears to depend on the baseline glycemic level. A meta-regression analysis of 61 clinical trials evaluated the efficacy of the five classes of oral agents (sulfonylureas, glinides, metformin, TZDs, and α-glucosidase inhibitors).[254] Significant correlations were found between the baseline A1C and FPG, and their mean decreases as a result of these agents. Greater reductions in A1C and FPG were observed in groups with higher baseline levels. In addition, a meta-analysis of oral agents found that every 1% higher baseline A1C level predicted a 0.5% greater reduction in the A1C after 6 months of therapy.[255] Overall, on initiation of noninsulin monotherapy, the A1C will typically lower by approximately 1% to 1.25%.[255]

If L.H. is not able to reach an A1C of less than 7% with lifestyle interventions, the next step for her would be to add a second antidiabetic agent. Selecting an antidiabetic agent to treat Type 2 diabetes has become more complex because new agents with unique mechanisms of action have been introduced into the market. Several considerations should be taken into account when choosing initial oral therapy for patients with Type 2 diabetes. As with all therapeutic decisions, clinicians should also blend their knowledge of the drug (e.g., its efficacy, safety, hypoglycemic risk, weight gain, other side effects, route of administration, and cost/hospital formulary) with the unique characteristics of the patient (e.g., level of glycemic control, organ function, other concurrent diseases and medications, ability to adhere to complex medication regimens, health insurance coverage) when making a choice of drug products.[256] The current A1C level and reduction required to reach the A1C goal is a key consideration. It is also important to remember that studies report the glucose-lowering effects of antidiabetic agents by their means; some patients respond more and some respond less than the mean.

Table 53-25 compares and contrasts the efficacy, advantages, and disadvantages of antidiabetic agents used to treat patients with Type 2 diabetes and can be used to help select drugs for a specific patient.

The AACE guidelines recommend consideration of initiating insulin therapy (most often basal insulin) if the A1C is more than 9% with symptoms of hyperglycemia.[39] The ADA guidelines recommend choosing based on patient's level of glycemia and if they are symptomatic.[7] It is an option for dual therapy in all patients, especially if A1C > 9%, but should be strongly considered with an A1C > 10%.[7] Practitioners should attempt to avoid unnecessarily complex therapy that may confuse the patient, increase drug costs, and complicate the clinician's ability to assess each medication's contribution to the overall therapeutic outcome.

The ADA recommends initial therapy with lifestyle changes and metformin monotherapy. If the patient cannot tolerate metformin, any other agent approved for monotherapy may be used. These agents include sulfonylureas, TZDs, DPP-4 inhibitors, SGLT2 inhibitors, GLP-1 receptor agonists, and insulin. Selection of appropriate agents will be discussed later in this chapter. If after 3 months of monotherapy the patient has not achieved their glycemic targets, a second agent may be added. If the patient still has not achieved their glycemic targets after 3 months of dual therapy, a third agent may be added. If glycemic targets still have not been reached after 3 months of triple therapy, different drug classes should be tried and a basal-bolus insulin approach may be considered.[7]

SELECTING AN ALTERNATIVE TO METFORMIN AS MONOTHERAPY

CASE 53-11, QUESTION 8: Which other antidiabetic agents could be considered for L.H. as monotherapy if she cannot tolerate metformin therapy?

Although the ADA recommends the use of metformin, in combination with lifestyle modification, as first-line therapy, other antidiabetic agents are approved for use as monotherapy as well. L.H. is a typical overweight Type 2 diabetes patient with early evidence of CVD (hypertension), but with no evidence of microvascular complications. Her liver, renal, and GI functions are normal. Patients like L.H. have varying degrees of β-cell dysfunction and tissue resistance to insulin. In these individuals, pulsatile insulin secretion and first-phase insulin release are absent, and the pancreas is "blind" or unresponsive to high glucose concentrations (glucotoxicity). Because target tissues are less responsive to insulin, hepatic glucose output typically is increased and higher concentrations of insulin may be needed for peripheral glucose utilization. Insulin causes more weight gain and hypoglycemia than the other antidiabetic agents and is usually reserved for combination therapy unless the initial A1C at diagnosis is very elevated (>10%) or ketonuria is present.[7]

Often, acarbose is eliminated from consideration because slow titration is required to minimize GI effects; anecdotally, however, people of Mexican American origin, such as L.H., seem less susceptible to flatulence and diarrhea. Also, because acarbose has less dramatic effects on the FPG (20–30 mg/dL decrease) and A1C (0.5%–1.0% decrease) than the other agents, biochemical goals are less likely to be achieved in patients whose A1C is 8.5% or higher.

Pioglitazone also can be used as monotherapy, and, like metformin, will not cause hypoglycemia, but weight gain and edema are likely. On the positive side, the TZDs have been shown to have better "glycemic durability" compared with metformin and the sulfonylureas. In a double-blind, randomized, controlled trial of 4,360 patients with Type 2 diabetes, time to monotherapy failure, defined as FPG greater than 180 mg/dL, was assessed for rosiglitazone, metformin, and glyburide (A Diabetes Outcome Progression Trial [ADOPT]).[257] Patients were treated for a median of 4 years. The Kaplan–Meier analysis showed that the cumulative incidence of failure at 5 years was 15% for rosiglitazone, 21% for metformin, and 34% for glyburide ($p < 0.0001$). The suggested explanation for the favorable rosiglitazone results was that it slowed the rate of β-cell function decline. On the negative side, TZDs are associated with many adverse effects

---

including an increase risk in bone fractures and HF.[258] TZDs are associated with an approximately twofold increased risk of HF and thus are contraindicated in NYHA Class III-IV HF.[185,187] In the long-term ADOPT trial, rosiglitazone was associated with a mean weight gain of 4.8 kg, whereas weight decreased by 2.9 kg in the metformin group; glyburide-treated patients had a mean weight gain of 1.6 kg during the first year, and then remained stable.[257] The TZDs also have been found to reduce bone density and increase fracture risk. Given the adverse effects associated with TZDs, and the availability of other agents, their use has fallen out of favor.

Sitagliptin, saxagliptin, and exenatide, which are approved for monotherapy, are often reserved for combination therapy. However, DPP-4 inhibitors may be useful as monotherapy for patients in whom the use of other oral agents is precluded (such as renal dysfunction with metformin or severe HF with pioglitazone). GLP-1RAs may be particularly useful in obese patients.[7,39] It should be noted that AACE recommends GLP-1RAs as first line if metformin can't be initiated first.[39]

Finally, one should not forget that until the newer agents became available, sulfonylureas were used quite successfully to treat obese patients with Type 2 diabetes. Although these agents are relatively effective (average A1C reduction 1%–1.5%), there are still several issues with this class of medications such as unfavorable adverse effects (hypoglycemia and weight gain), durability issues, and may worsen the lipid panel. Although the use of these agents has fallen out of favor due to these effects, they are effective and often utilized when cost is an issue (Table 53-26).

Several products that combine two oral agents into one medication are available. Although many of these products are approved as first-line therapy, thus skipping the monotherapy step, consider reserving them for use in patients who are already established on the two agents or whose medication regimens must be simplified to enhance adherence or decrease cost or are already established on the two agents.

Based on this discussion, metformin is favored as initial therapy in L.H.

CASE 53-12

QUESTION 1: N.H. is a 46-year-old, obese (BMI 33 kg/m^2) man with a history of Type 2 diabetes, and hyperlipidemia. He presents with complaints of fatigue and nocturia. N.H. used to smoke two packs of cigarettes/day for 15 years, but he quit after his diabetes diagnosis. He has a strong family history of CHD. At diagnosis 3 months ago, an elevated A1C was documented (7.6%), confirming the diagnosis of Type 2 diabetes. Tests of liver and renal function are within normal limits. Current medications include lisinopril and atorvastatin. N.H. started metformin but stopped taking it because of GI symptoms (loose stools); he refuses to try this medication again. What is a reasonable next monotherapy option for N.H.?

Unfortunately, N.H. did not tolerate metformin. Although this is less common if patients take metformin with food and the dose is titrated slowly, some do not overcome the GI adverse effects. N.H. is refusing to even consider a retrial. An A1C goal of less than 7% may be appropriate for N.H., although given his young age and long life expectancy, a target of less than 6.5% would be preferred. Therefore, the A1C lowering required to get to goal is only 0.6% to 1.1%.

With a BMI of 33 kg/m^2, hypertension, and dyslipidemia, N.H. has many components of the metabolic syndrome and insulin resistance (see Pathogenesis section). Sulfonylureas or insulin would not be an optimal next choice of drug for N.H. because they do not exert a favorable effect on plasma lipids and generally are associated with weight gain and hypoglycemia. Also, his A1C is not high enough to need insulin therapy yet. However, it must be acknowledged that some sulfonylureas remain the least expensive oral antidiabetic agents, and this may be an important factor in the initial selection of therapy for some patients. Acarbose as monotherapy is not likely to attain near-normal plasma glucose concentrations. Given he is obese, and likely insulin resistant, although pioglitazone improves peripheral target tissue responses to insulin and lipid profiles, avoiding pioglitazone due to adverse effects of weight gain is prudent (see Case 53-11, Question 8, and Case 53-15). A GLP-1 agonist, DPP-4 inhibitor, or SGLT-2 inhibitor are reasonable options for N.H. because they are not associated with weight gain (GLP-1 agonists and SGLT-2 inhibitors may even promote weight loss).

For N.H., initiation of a GLP-1RA, such as liraglutide, is a reasonable option. A GLP-1RA, along with lifestyle changes, should be able to get to his A1C goal. If liraglutide is used, it should be initiated at a dose of 0.6 mg once daily for 1 week and then increased to the therapeutic dose of 1.2 mg once daily thereafter. Some patients may require further titration to 1.8 mg once daily in order to reach their glycemic goals. N.H. should be counseled about the likelihood of GI side effects, which should subside over time, as well as the rare risk of pancreatitis (and to stop taking and notify his provider if he has persistent severe abdominal pain that may radiate to the back and vomiting) and severe allergic reactions.

N.H. was successful in reducing his A1C to 6.4% through a combination of lifestyle modifications and sitagliptin. He was able to lose 10 lb with walking and reduction in fatty food.

N.H. quit smoking 3 months ago. Smoking has been shown to increase the risk of IFG and Type 2 diabetes.[259,260] The mechanism for this is thought to be related to increased insulin resistance and oxidative stress and reduced insulin secretion. Smoking also increases the risk of microvascular and macrovascular disease in people with diabetes.[261] Therefore, N.H. should be congratulated on his cessation, and continued abstinence should be encouraged through follow-up visits (see Chapter 91, Tobacco Use and Dependence).

Failure of Antidiabetic Monotherapy

PATHOGENESIS

CASE 53-13

QUESTION 1: Q.R. is a 68-year-old, 5 feet 1 inch, 155-lb (BMI, 29.3 kg/m^2) woman with an 8-year history of Type 2 diabetes who has been treated with diet, exercise, and metformin. According to clinic records, she was well controlled initially (A1C 6.7%–7.2%) for the first 5 years. When her glycemic control worsened (FPG, 130–160 mg/dL; A1C, 7.5%–8.5%), her metformin dose was increased from an initial dose of 500 mg BID to her current dose of 1,000 mg BID. Recent chart notes indicate that Q.R.'s chief complaints have included loss of appetite and fatigue. Her current A1C is 8.4%. Other medical problems include hypertension managed with hydrochlorothiazide 25 mg daily and mild peripheral neuropathy managed with acetaminophen 500 mg BID. Her eGFR is 70 mL/minute.

At this clinic visit, Q.R., who is well known to you, seems particularly listless and flat in her affect. Her BG records, which are typically meticulous, are incomplete. AM fasting BG values consistently exceed 200 mg/dL and range from 202 to 340 mg/dL. While taking her history, you discover that her husband passed away last year and that one of her adult children has recently been diagnosed with a terminal illness. What factors may be contributing to Q.R.'s poor glucose control?

Several factors may be contributing to Q.R.'s deteriorating BG control and apparent lack of responsiveness to maximal dose of metformin during the past year (as evidenced by her elevated BG and A1C, listlessness, and lack of appetite). Monotherapy failure (also called secondary failure) is characterized by progressively poor glucose control that occurs after a period of good response (months to years). The cause of failure may be related to progressive pancreatic failure; poor adherence to diet, exercise, or medications; and exogenous diabetogenic factors such as increased weight, illness, or drugs that induce hyperglycemia (e.g., atypical antipsychotics or glucocorticoids).

Type 2 diabetes is a progressive condition, which is most likely to require combination drug therapy. The UKPDS confirmed that monotherapy failure represents a natural progression of Type 2 diabetes. In this study, only 16% and 19% of the subjects achieved an FPG less than 108 mg/dL and A1C less than 7%, respectively, after 3 years of dietary therapy alone.[262] By 9 years, only 9% were able to maintain their glycemic goals using just diet therapy. The investigators also found monotherapy failure occurred at the same rate regardless of the initial treatment selected: glyburide, chlorpropamide, metformin, or insulin. In all the monotherapy treatment groups, patients required additional therapies over the course of the study duration.[262] At 3 years, fewer than 55% of patients randomly assigned to single pharmacologic therapy could maintain an A1C less than 7%, and by 9 years this dropped to about 25% of patients. In the ADOPT study, patients were able to maintain A1C levels less than 7% using monotherapy for 60, 45, and 33 months with rosiglitazone, metformin, and glyburide, respectively.[257] The reason for glycemic deterioration is likely owing to the natural progression of Type 2 diabetes in which β-cell function declines with increased duration of disease.

Q.R.'s deteriorating control on a therapeutic dose of metformin after 5 years of reasonable response is consistent with the natural progression of Type 2 diabetes. However, the stress and depression arising out of her life situation have no doubt contributed to her poor control. The latter may have led to a change in her usual adherence to diet, exercise, and medications, and should resolve with time and appropriate management. Women with Type 2 diabetes are at increased risk of depression. Evidence exists for a bidirectional association between diabetes and depression in women.[263] Although hyperglycemia has been attributed to hydrochlorothiazide, the dose prescribed for Q.R. has few adverse metabolic effects.

MANAGING MONOTHERAPY FAILURE

CASE 53-13, QUESTION 2: How should Q.R. be managed? What is an appropriate antidiabetic agent to add?

Q.R. is exhibiting symptoms of depression (e.g., listlessness and flat affect). Her depression likely started after her husband's death. Every effort must be made to address Q.R.'s depression because it is unlikely that she will be able to effectively implement more aggressive treatment of her diabetes until her situation is improved. Resources that may be used include her family, a therapist, and a social worker.

Treatment of monotherapy failure includes identifying and correcting any diabetogenic factors and altering her drug therapy. When failure to any oral agent occurs, one should always add another agent rather than switch to another, unless adverse effects are intolerable or contraindications warrant the discontinuation of the drug. This is supported by a study that evaluated the effect of metformin alone in a population of patients who had failed oral sulfonylureas and the effect of metformin plus the sulfonylureas. Substitution of metformin for glyburide did not produce any significant change in glycemic control, but the addition of metformin to glyburide therapy substantially improved glucose concentrations.[264] Many combinations of antidiabetic agents can be used. The key is that they should have different mechanisms of action. For example, it is not reasonable to combine a sulfonylurea with a glinide (i.e., repaglinide and nateglinide) because they are both insulin secretagogues. Options for Q.R. include adding one of the following to metformin: insulin secretagogue (sulfonylurea or glinide), acarbose, TZD (pioglitazone), DPP-4 inhibitor (sitagliptin, linagliptin, alogliptin or saxagliptin), SGLT-2 inhibitors (canagliflozin, dapagliflozin, empagliflozin), or a GLP-1 agonist (exenatide, exentatide ER, albiglutide, dulaglutide, or liraglutide). SGLT-2 should be used cautiously in this patient because this drug class is associated with genital mycotic infections and urinary tract infections.[228]

Table 53-25 summarizes the FDA-approved combination therapy indications. One also could introduce insulin therapy at this time. However, because Q.R.'s A1C should be effectively lowered to less than 7% with an additional noninsulin agent, two noninsulin antidiabetic agents should be utilized.

In summary, patients such as Q.R. who are unresponsive to the maximally effective dose of metformin should be initiated on combination therapy.

Combination Antidiabetic Therapy

CASE 53-13, QUESTION 3: As anticipated, Q.R. refuses to consider insulin therapy at this time. Which combination of antidiabetic agents is preferred?

When agents from different antidiabetic classes are combined, their effects are essentially additive. With the availability of many antidiabetic agents, there is no one best combination therapy. As discussed, the choice of therapy should take into account the patient's organ function, amount of A1C lowering required to reach an individual's goal, possible adverse effects of a particular drug or drug combination, cost, and patient preference.

A mixed-treatment comparison meta-analysis evaluated the efficacy of second-line antidiabetic therapy added to patients on stable doses of metformin.[265] The risk of weight gain and hypoglycemia was also determined. A total of 27 randomized controlled trials were included in the analysis, with a mean study duration of 32 weeks. Table 53-27 summarizes these findings. In addition, the change in A1C depending on the baseline level of A1C was evaluated and found, as previously discussed (see Case 53-11, Question 7), to be greater when the baseline A1C was 8% or more.

Q.R. is concerned with the costs of her medications, and brand drugs have a higher copay in her insurance plan. Q.R. would like to remain on oral medications if possible. Because she is postmenopausal, avoid a TZD owing to the concerns of increased risk of fractures. Given the significant GI side effects associated with the α-glucosidase inhibitors, their use is often avoided all together. The DPP-4 inhibitors are available by brand only, so initiating a generic is an option. Therefore, she is started on glimepiride 2 mg PO daily.

Combination Antidiabetic Therapy

CASE 53-13, QUESTION 4: Q.R. is titrated to glimepiride 4 mg/day and continued on metformin 1,000 mg BID. This improved her FPG and A1C modestly for approximately 12 months (FPG, 120–150 mg/dL; currently A1C, 7.6%). She remains resistant to starting insulin, despite repeated counseling. She has heard about a new, injectable class of diabetes medications that cause weight loss, and asks whether she is a good candidate to start one. It quickly becomes apparent that Q.R. is referring to the GLP-1 agonists, exenatide, exenatide ER, dulaglutide, albiglutide, and liraglutide; only exenatide is on her health plan's formulary.

Table 53-27

Effects of Adding a Noninsulin Antidiabetic Agent in Patients with Type 2 Diabetes Already on Metformin[265]

	Effects of Adding a Noninsulin Agent Compared with Placebo in Patients Taking Metformin on Change in A1C, Body Weight, and Hypoglycemia					
	% Change in A1C		Change in Body Weight (kg)		Overall Hypoglycemia	
Group vs. Placebo	No. of Trials	WMD (95% CI)	No. of Trials	WMD (95% CI)	No. of Trials	RR (95% CI)
All drugs	20	−0.79 (−0.90 to −0.68)	12	−0.14 (−1.37 to 1.65)	19	1.43 (0.89 to 2.30)
SFUs	3	−0.79 (−1.15 to	2	−1.99 (0.86 to 3.12)	3	2.63 (0.76 to 9.13)

		−0.43)				
Glinides	2	−0.71 (−1.24 to −0.18)	2	−0.91 (0.35 to 1.46)	2	7.92 (1.45 to 43.21)
TZDs	3	−1.00 (−1.62 to −0.38)	1	−2.30 (1.70 to 2.90)	2	2.04 (0.50 to 8.23)
AGIs	2	−0.68 (−1.11 to −0.19)	1	−1.80 (−2.83 to −0.077)	2	0.60 (0.08 to 4.55)
DPP-4 inhibitors	8	−0.79 (−0.94 to −0.63)	4	−0.09 (−0.47 to 0.30)	8	0.67 (0.30 to 1.50)
GLP-1 agonists	2	−0.99 (−1.19 to −0.78)	2	−1.76 (−2.90 to 0.62)	2	0.94 (0.42 to 2.12)

	Effects of Adding a Noninsulin Agent Compared with Placebo in Patients Taking Metformin on Change in A1C, Depending on Baseline A1C	
	Baseline A1C	
Group vs. Placebo	**<8% WMD (95% CI)**	**≥8% WMD (95% CI)**
SFUs	−0.57 (−0.75 to −0.39)	−0.97 (−1.35 to −0.62)
Glinides	−0.44 (−0.85 to −0.04)	−0.65 (−1.10 to −0.26)
TZDs	−0.62 (−0.88 to −0.39)	−1.02 (−1.39 to −0.69)
AGIs	NR	−0.65 (−1.07 to −0.24)
DPP-4 inhibitors	−0.51 (−0.69 to −0.34)	−0.89 (−1.11 to −0.68)
GLP-1 agonists	NR	−0.99 (−1.36 to −0.63)

Results are from a subgroup mixed-treatment comparison meta-analysis.

AGIs, α-glucosidase inhibitors; CI, confidence interval; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; NR, not reported; RR, relative risk; SFUs, sulfonylureas; TZDs, thiazolidinediones; WMD, weighted mean difference.

When the A1C is above goal despite the use of a combination of two agents, practitioners often add a third agent before considering insulin. Although this is tempting, depending on a patient's current level of glycemic control, this practice only delays insulin therapy, which is likely to be required to achieve A1C goals. However, because Q.R. is close to an A1C level of less than 7%, it is reasonable to try a third, noninsulin antidiabetic agent. Although glimepiride 8 mg/day is the maximal dose, there is little difference in clinical efficacy compared with 4 mg/day. Therefore, increasing glimepiride to 8 mg/day is not likely to achieve her glycemic goals.[266]

Exenatide is approved for use in patients as monotherapy and also for those taking metformin, sulfonylurea, or a TZD alone, or a combination of metformin plus a TZD or metformin plus a sulfonylurea. When added to patients on a sulfonylurea and metformin, exenatide at 10 mcg BID resulted in a 0.8% A1C reduction compared with baseline.[258] Thus, for Q.R., the addition of exenatide could result in an A1C of less than 7%. The use of exenatide with a sulfonylurea is associated with an increased risk of mild-to-moderate hypoglycemia (28% when used with sulfonylurea and metformin and 36% when used with sulfonylurea alone).[258,267] Most practitioners reduce the dose of the sulfonylurea on initiation of exenatide and then make adjustments based on the patient's response to exenatide.

Q.R. should be started on exenatide 5 mcg SC BID, taken within 60 minutes of the two main meals of the day and at least 6 hours apart. She should be counseled about nausea, which is the most frequent side effect; 44% of patients will experience nausea, but there is only a 3% dropout rate in the clinical trials. The glimepiride should be reduced to 2 (or 3) mg/day to avoid hypoglycemia. After 1 month, if she is tolerating exenatide, the dose should be increased to 10 mcg SC BID. Her A1C should be monitored within 3 months of using the 10-mcg dose. An advantage of exenatide (versus DPP-4 inhibitors) is the potential for weight loss. In a 30-week blinded study of exenatide added onto sulfonylurea and metformin, patients on the 10-mcg dose had an average weight loss of 1.6 kg.[258] In the three open-label, uncontrolled extension trials with exenatide, at 3 years, exenatide progressively reduced (−5.3 kg) and sustained weight loss.[268]

Q.R. should be counseled about the rare risk of pancreatitis. Also, if she finds that nausea is significant enough to reduce her fluid intake, she should contact her provider. The FDA has received case reports of altered renal function and renal failure with exenatide, which are likely owing to dehydration from reduced fluid intake because of the GI side effects (i.e., nausea, vomiting, and diarrhea) caused by exenatide.[214] In patients with significant GI side effects, reduced fluid intake, or preexisting renal dysfunction, the SCr should be monitored more closely. Exenatide should be used cautiously with moderate renal impairment and is not recommended in patients with ClCr of less than 30.[214]

A small proportion of patients will form antiexenatide antibodies. At high titers, these antibodies could result in failure to achieve adequate improvement in glycemic control. If there is worsening glycemic control or failure to achieve targeted glycemic

---

control while on exenatide, the formation of blocking antibodies should be considered as a reason. If this occurs, it may be reasonable to switch over to another GLP-1 analog or exenatide ER. It is important to note that any of the available GLP-1 RAs are options for Q.R. for initial GLP-1 RA therapy. Discussions should be regarding adherence, efficacy, side effects, and cost.

Combination Antidiabetic with Insulin Therapy

CASE 53-13, QUESTION 5: If Q.R. were willing to start insulin, why would it be reasonable to use insulin in combination with other antidiabetic agents? How should it be combined with other agents? Is this combination more effective than insulin alone?

Most patients with Type 2 diabetes eventually require insulin. The combined use of insulin with a variety of oral agents has been extensively evaluated, but the studies differ in their interventions. In some studies, single doses of an intermediate- or long-acting insulin or once- or twice-daily doses of premixed insulin are added to a single or combination of oral antidiabetic agents in poorly controlled patients. The primary outcomes that have been evaluated include measures of glycemic control (e.g., A1C, FPG) and the extent to which insulin doses have been decreased. DeWitt and Hirsch published a comprehensive review of these studies, and readers are referred to this article for this evidence.[93] The combined use of insulin and oral agents can be considered based on the ACCE algorithm, particularly when the A1C is higher than approximately 9%.

Before starting insulin, it is important to review the BG profile:

- Fasting hyperglycemia, which may improve or persist throughout the day. This is t more typical glucose profile for patients with Type 2 diabetes, in whom addition of basal insulin at nighttime would be the most appropriate next step.
- Fasting BG is at target, with daytime hyperglycemia. This is less common for people with Type 2 diabetes, in whom addition of prandial insulin would be an appropriate next step for therapy (see Case 53-13, Question 6).

In Q.R.'s case, it makes the most sense to add a single dose of basal insulin to metformin and glimepiride, with the potential to discontinue glimepiride once the insulin dose is optimized. Advantages attributed to adding insulin to an oral agent as the next step after failure, as opposed to using insulin alone, include the following[93]:

- Lower-insulin dosages can be used, and this minimizes weight gain and hypoglycemia.
- Simpler, single-dose insulin regimens are possible (vs. monotherapy with insulin)
- Lowering the fasting glucose concentrations improves glucose control throughout t day because glucose excursions related to meals are layered over lower values. Furthermore, lower glucose values improve β-cell responsiveness to glucose and enhance tissue responsiveness to insulin action.

However, lowering glucose concentrations is the first priority, not attempting to use lower-insulin doses. Q.R. should be started on 10 units or 0.2 unit/kg of NPH, or basal insulin glargine, detemir or degludec. This dose is based on empiric use of insulin in a variety of studies (0.1–0.2 units/kg)[269] and a conservative estimate for basal insulin of approximately 0.5 units/hour (Q.R. weighs 155 lb, or 70.5 kg). The dose also takes into account the possibility that Q.R. is secreting some basal insulin of her own and will have some residual stimulation of insulin secretion by glipizide. The basal dose should be titrated upward based on the FPG for three consecutive days. A common titration method used is the "treat-to-target" schedule.[92,270]

FPG (mg/dL)	**Adjustment of Basal Insulin Dose (Units)**
≥180	8

160–180	6
140–159	4
120–139	2
100–119	1
80–99	Maintain dose
60–79	−2
<60	−4 or more

Alternatively, the basal insulin dose can be increased by 2 units every 3 days until the FPG is in a target range (80–130 mg/dL); if the FPG is greater than 140 to 180 mg/dL, larger increments can be used (e.g., by 4 units every 3 days).[269] If hypoglycemia occurs or the FPG is less than 70 mg/dL, the dose should be reduced by at least 4 units, or by 10% if the dose is more than 60 units. Of note, U300 glargine and U100 and U200 degludec should not be titrated sooner than every 3 to 4 days. If there is no improvement in glycemic control after 3 months, prandial insulin or a GLP-1RA should be added (see Case 53-13, Questions 6 and 7). At that point, the insulin secretagogue (in Q.R.'s case, glimepiride) is usually discontinued, but metformin should be maintained.

An alternative for Q.R. is to discontinue the sulfonylurea and begin insulin monotherapy using methods similar to those described for Type 1 diabetes patients. This option also is rational based on the observation that patients like Q.R. are likely to require insulin therapy because of progressive β-cell failure. Furthermore, insulin monotherapy may be less expensive and easier to assess than combination oral agents plus insulin therapy. Nevertheless, many clinicians use single doses of basal insulin in combination with oral agents as a bridge to eventual insulin monotherapy, especially for those patients unwilling to adhere to multiple daily insulin injections. In the setting of insulin resistance, such as with Type 2 diabetes, continuing metformin therapy should be a priority if at all possible.

Insulin Monotherapy in Patients with Type 2 Diabetes

INSULIN REGIMENS

CASE 53-13, QUESTION 6: Q.R.'s insulin glargine dose was eventually titrated to 25 units at bedtime. In combination with glimepiride 4 mg/day and metformin 1,000 mg BID, her fasting glucose levels fell to the 110s and 120s on most occasions; her A1C dropped to as low as 6.9%. However, after 1 year, she began to note a gradual rise in glucose concentrations throughout the day. This resulted in a further increase in her bedtime insulin glargine to 40 units (0.57 units/kg). Currently, her morning BG levels are 120 to 140 mg/dL, and BG levels before or after meals range between 170 and 200 mg/dL. A recent A1C value was 8.5%. For the past 6 months or so, Q.R. has noted increasing fatigue, bouts of blurred vision, and recurrence of her monilial infections. How should she be managed now?

The next step in managing Q.R.'s diabetes is to institute prandial insulin therapy, which is needed as indicated by her daytime hyperglycemia. Like Type 1 diabetes patients, those with long-standing Type 2 disease may require prandial insulin before meals to minimize postprandial excursions. Insulin lispro has been shown to decrease postprandial glucose concentrations to a greater extent than regular insulin (30% lower at 1 hour and 53% lower at 2 hours) and was associated with a lower rate of hypoglycemia, particularly between midnight and 6 AM (36%). However, A1C levels were not significantly different after 6 months.[271] A similar response with insulin aspart and glulisine would be expected.

Because Q.R. is on insulin glargine, the most appropriate next step is to add prandial insulin using a rapid-acting insulin. Initiation of basal-bolus insulin regimens are discussed in detail in the Type 1 Diabetes Insulin Therapy section (see Case 53-2, Questions 4–6). An easy way to introduce prandial insulin is to initially add only one mealtime dose. The premeal BG levels that are associated with the most hyperglycemia are targeted. For example, if the prelunch BG levels are elevated, a prandial dose at breakfast is added; or if the bedtime BG levels are mainly elevated (owing to large dinners), a prandial dose at dinner is added. Once a patient adjusts to this, prandial insulin is added to the other meals; at that point glimepiride dose should be reduced or discontinued, altogether. Patients with Type 2 diabetes may require large insulin TDDs (>1 unit/kg) to reach A1C targets less than 7%. Although not technically insulin monotherapy, metformin is often continued to assist in reducing insulin resistance and minimizing weight gain with insulin.

PREMIXED INSULINS

CASE 53-13, QUESTION 7: Q.R. has difficulty adhering to a basal-bolus insulin regimen. She is currently taking insulin glargine 38 units at nighttime and approximately 7 units of insulin aspart before each meal (she follows a high-sugar correction scale). What options are available for Q.R.?

Because people with Type 2 diabetes retain some pancreatic function, it often is possible to achieve an acceptable level of control with twice-daily doses of intermediate-acting insulin in combination with rapid- or short-acting insulins, which are available as premixed insulins. These are referred to as split-mixed insulin regimens. Although convenient, they do limit flexibility in dosing, and thus A1C lowering ability without increasing hypoglycemia risk. In the United States, fixed mixtures of NPH and regular insulin in a 70:30 ratio and a 50:50 ratio are available (Table 53-6). Commercial combinations of the rapid-acting insulins plus an intermediate-acting insulin also are available as Humalog Mix 75/25 (a mixture of insulin lispro plus lispro protamine suspension), Humalog Mix 50/50 (a mixture of insulin lispro plus lispro protamine suspension), and NovoLog Mix 70/30 (a mixture of insulin aspart plus aspart protamine suspension). These fixed mixtures are available in prefilled syringes, which can add to their flexibility and convenience for administration.

The Treating to Target in Type 2 Diabetes (4-T) study assessed the efficacy of a basal insulin (detemir), prandial insulin (insulin aspart), and biphasic insulin (NovoLog Mix 70/30) regimen added to patients on metformin and a sulfonylurea.[272] After 3 years, a biphasic-based insulin regimen was found to be less effective in achieving an A1C goal of less than 6.5% compared with prandial and basal insulin regimens (31.9%, 44.7%, and 43.2%, respectively). Despite the findings of this large multicenter study, use of twice-daily, premixed insulin remains a common insulin therapy for patients with Type 2 diabetes.

Q.R. is currently receiving a TDD of insulin of 59 units, or 0.84 units/kg/day. To convert her to a premixed insulin, one could begin with a conservative TDD of 0.5 to 0.6 units/kg/day, split equally before breakfast and dinner. An older method of two-thirds in the morning and one-third in the evening is used less commonly now. When starting an insulin-naïve Type 2 diabetes patient on premixed insulin, doses of 5 to 6 units twice daily (administered before breakfast and dinner) are often used, with the doses being titrated before breakfast (to affect prelunch and predinner glucose levels) and before dinner (to affect the bedtime and fasting glucose levels).[92,273]

If the premixed insulin does not achieve adequate glycemic control, an option is to mix the short- or rapid-acting insulin with NPH in the same syringe. By doing this, each insulin dose can be individually adjusted. A disadvantage to this is the chance for patients to make errors in measuring and mixing insulin, especially in the elderly when they may have vision and/or dexterity issues. Alternatively, a prandial dose of rapid-acting insulin (i.e., a third injection) can be added at lunch; the breakfast dose of premixed insulin should be decreased as well.[93] Another option is to add a third dose of the premixed insulin at lunch (so premix insulin TID); however the lunchtime dose is smaller than the breakfast and dinner dose. An initial premixed insulin lunchtime dose of 2 to 6 units, or 10% of the current TDD of premixed insulin, can be started.[274]

Q.R. should be started on a rapid-acting premixed insulin twice daily, as this has the convenience of being administered right before eating (within 15 minutes). A dose of 20 units SC BID represents a conservative starting dose. She should monitor her fasting and predinner BG levels, at a minimum, to further adjust her insulin doses.

Adding Antidiabetic Agents to a Basal Insulin Therapy-Based Regimen

CASE 53-14

QUESTION 1: M.A., a 62-year-old woman, has had Type 2 diabetes for 11 years. She is currently taking metformin 500 mg PO TID and insulin glargine 47 units at bedtime. Her A1C is 8.2%. She tries to follow a meal plan that a dietitian developed for her, but her BMI remains 31 kg/m^2. Her physical activity is limited because of an arthritic knee, for which she plans to have knee replacement surgery in the future. Other medical problems include hypertension (hydrochlorothiazide 25 mg daily and benazepril 40 mg daily) and dyslipidemia (atorvastatin 40 mg daily), which are both well controlled. Can any antidiabetic agents be added to her current therapy?

The TZDs have been well studied in patients with Type 2 diabetes who are already taking insulin. In a meta-analysis, pioglitazone lowered A1C by 0.58% when added to insulin therapy; unfortunately, it was associated with weight gain (3 kg) and increased peripheral edema and therefore should be avoided.[206]

A GLP-1 agonist would be a logical agent to considering adding in obese patients. Any GLP-1RA would be a good option. The agents should be chosen based on cost, effectiveness, and adherence. For example, exenatide may be the only GLP-1RA on formulary, or perhaps M.A. has trouble remembering to take once-weekly medications, such as dulaglutide, and as such would be more successful with once-daily liraglutide. Adding a DPP-4 inhibitor would be another option. Sitagliptin is FDA-approved for use with insulin; however, the A1C lowering may be less than with a GLP-1 agonist.

Therefore, addition of liraglutide may be a reasonable approach in M.A. Her A1C can reach her target goal of less than 7%, with potential for weight loss and lower-insulin glargine requirements. Liraglutide should be initiated at a dose of 0.6 mg injected SC once daily for 1 week, after which the dose should be increased to 1.2 mg once daily. Some patients may require further titration to a maximum dose of 1.8 mg once daily to reach their glycemic targets.

Use of Antidiabetic Agents in Special Situations

HYPOGLYCEMIA

CASE 53-15

QUESTION 1: C.A. is a 73-year-old woman who has had a 20-year history of Type 2 diabetes and a 5-year history of mild renal dysfunction (SCr, 1.2 mg/dL; eGFR, 47 mL/minute/1.73 m^2; BUN, 22 mg/dL). Her son, who lives with her, quickly called 9-1-1 when he noticed his mother appearing lethargic and sleepy, with her eyes closed, as she was sitting on the couch. He assumed she was having a "low sugar reaction." When the paramedics arrived, her BG concentration was 46 mg/dL. C.A. was able to be aroused, and indicated she could drink something, so 4 ounces of orange juice was administered. After 10 minutes, her BG level was 80 mg/dL, so she was given another 4 ounces of juice. According to her son, C.A.'s diabetes has been well controlled for the past several months with glyburide 10 mg BID and metformin 850 mg TID. For the past 3 days, C.A. has been eating less and vomiting on association, with the "flu." What was the likely cause of her hypoglycemic episode? Were there any predisposing factors?

C.A. has experienced a hypoglycemic episode secondary to glyburide.

Hypoglycemia is the most common and potentially severe adverse effect of the sulfonylureas. The incidence and severity of this effect increase with the duration of action and potency of the agents.

Most sulfonylurea-induced hypoglycemia occurs in patients who are predisposed to hypoglycemia in some way, and C.A. is no exception. She is an elderly woman with renal impairment who was on relatively high doses of an agent, a portion of which is excreted unchanged in the urine. Even in the face of decreased carbohydrate intake (reduced appetite and vomiting), she continued to take her usual dose of glyburide. Even though the stress of illness most often raises glucose levels, the decreased food intake resulted in glyburide causing hypoglycemia. Because glyburide has a long duration of action, hypoglycemia may last for several hours.

C.A. and her son should be educated about treatment of hypoglycemia. It is likely that her son did not need to call 9-1-1, and he could have treated the hypoglycemia. Glucagon should not be used to treat hypoglycemia caused by a sulfonylurea, as glucagon can cause a paradoxical fall in the glucose levels.[275]

RENAL DYSFUNCTION

CASE 53-15, QUESTION 2: C.A. has mild renal insufficiency (eGFR, 47 mL/minute/1.73 m^2) and is taking the maximal dose of metformin. What is the risk of lactic acidosis with metformin? How should age and kidney function be taken into account with metformin use? Which agents should be avoided? Which agents could be used?

Sulfonylurea compounds that are metabolized to active products that depend on the kidney for elimination (e.g., acetohexamide, chlorpropamide glyburide, and tolazamide) should be avoided in the elderly and in patients with decreased renal function. Sulfonylureas that are completely metabolized to inactive or weakly active products may be used (i.e., glipizide, glimepiride, or tolbutamide). Although glyburide is unlikely to accumulate in patients with a ClCr greater than 30 mL/minute, it should not be used in C.A because it caused a severe hypoglycemic reaction.[276] C.A. should be instructed to eat regularly because skipped meals may result in recurrent hypoglycemia. Consideration to discontinuing the sulfonylurea and changing adding an agent with a lower incidence of hypoglycemia should be considered.

The most notorious side effect associated with metformin—although extremely rare—is lactic acidosis. The risk of lactic acidosis is increased with renal insufficiency, which can result in accumulation of metformin because it is almost exclusively clear unchanged by the kidneys. Lactic acidosis is a metabolic acidosis characterized by a significant reduction in the arterial pH and an accumulation of serum lactate, a product of anaerobic metabolism. It is a condition that is highly lethal (50% mortality) and resistant to therapy. Lactic acidosis occurs when there is an increased production of or decreased utilization of lactate. Decreased utilization of lactate occurs when tissues are unable to oxidize lactate to pyruvate (these two substances are normally present in the serum in a ratio of 10:1). Metformin might predispose a patient to lactic acidosis by augmenting anaerobic metabolism or by decreasing the kidney's ability to handle an acid load. Other factors that might contribute to lactic acidosis include severe cardiac or pulmonary disease (anoxia, increased lactate production), septic shock, renal dysfunction (retention of metformin and lactate), patients receiving contrast dye, and excessive alcohol intake (increased lactate production and decreased utilization).[165–167]

Signs and symptoms generally are acute in onset and commonly include nausea, vomiting, diarrhea, and hyperventilation. Hypovolemia, hypotension, confusion, and coma also may occur; death is usually secondary to cardiovascular collapse. Typical laboratory findings include a low serum bicarbonate and P_{CO_2}, a low arterial pH, an elevated potassium, a normal or low serum chloride, elevated lactate and pyruvate levels, an increased lactate to pyruvate ratio, and an anion gap of 30 mEq/L or higher.

Although metformin rarely is associated with lactic acidosis, the manufacturer and the FDA have taken extreme measures to prevent its improper use because another biguanide, phenformin, which induced this life-threatening condition, was removed from the market in 1977.[277] The estimated rate of phenformin-induced lactic acidosis was 0.25 to 4 cases per 1,000 users versus 5 to 9 cases per 100,000 users for metformin.[165–167] A group of clinicians from the FDA summarized 47 confirmed cases of metformin-related lactic acidosis (lactate levels ≥5 mmol/L) that had been reported to the FDA between May 1995 and June 1996.[261] Unfortunately, the condition continues to be resistant to treatment; the mortality rate was 43%. Importantly, 43 of the 47 cases (91%) had concurrent conditions that predisposed them to lactic acidosis. These included cardiac disease (64%), decreased renal function (28%), and chronic pulmonary disease (6%). Several patients (17%) were older than 80 years of age and may have had decreased renal function despite normal SCr concentrations. Interestingly, 38% of the patients had HF, and those who died were more likely to be under treatment with digoxin and furosemide. The mean daily dose of metformin was well within the therapeutic range and was not higher in the group that succumbed (1,259 ± 648 mg in the group that died and 1,349 ± 598 mg in the group that survived).

Metformin should be initiated with care in patients older than 80 years of age because of the potential for a low GFR, even when SCr is normal.[164] Because C.A. has moderate renal dysfunction (GFR <60 mL/minute, but >40 mL/minute), lower the dose of metformin to 500 mg BID to minimize the potential for accumulation.

The TZDs are primarily metabolized by the liver and are not contraindicated in patients with mild renal failure. The use of pioglitazone, beginning with low doses, could be considered, as can acarbose, which is poorly absorbed from the GI tract. The DPP-4 inhibitors could also be used, but their doses may require adjustment depending on the degree of renal dysfunction (except for linagliptin). Exenatide can be used in patients with ClCr greater than 30 mL/minute, and the dose does not need to be adjusted.

Liraglutide should be used with caution in renal insufficiency, but does not require dose adjustment. None of these agents cause hypoglycemia when used as monotherapy.

HEPATIC DYSFUNCTION

CASE 53-16

QUESTION 1: B.R., a 60-year-old man with cirrhosis of the liver, is found to have Type 2 diabetes. Glipizide 10 mg/day is initiated. How will B.R.'s liver function affect the disposition of glipizide and his response to this agent?

Most noninsulin antidiabetic agents should be avoided in patients with severe liver disease, and insulin therapy is often the safest option. Because hepatic metabolism is the primary route of elimination for most sulfonylureas, including glipizide, patients with hepatic disease should be expected to have an exaggerated response to those drugs metabolized to less active products. Liver disease can be a separate predisposing factor for severe, prolonged hypoglycemia because glycogenolysis and gluconeogenesis are impaired; thus, sulfonylureas are relatively contraindicated for cirrhotic patients. If they are used, shorter-acting agents are preferred, and small initial doses should be used. For B.R., glipizide could be initiated at a dose no greater than 2.5 mg/day and increased if needed by 2.5-mg increments at no less than weekly intervals. Other options are low doses of repaglinide (0.5 mg) or nateglinide (60 mg) with meals because they are very short acting. Other good options for which severe liver disease is not a specific contraindication include GLP-1RAs, DPP-4 inhibitors, and SGLT2 inhibitors, although there is little data regarding their use in these patients. Basal-bolus or mixed insulin regimens are also good choices.

Diabetes in the Elderly

CLINICAL PRESENTATION

CASE 53-17

QUESTION 1: J.M. is a frail, 82-year-old, unresponsive man who is brought to the emergency department. According to J.M.'s family, he has become increasingly confused, dizzy, and lethargic, with a recent weight loss of 10 lb. J.M. lives by himself and has been generally healthy with the exception of mild-to-moderate chronic obstructive pulmonary disease and arthritis. Fasting serum chemistry reveals the following:

Na, 128 mEq/L
Glucose, 798 mg/dL
Serum osmolality, 374 mOsm/L (normal, 280–295 mOsm/kg H_2O)
Blood pH, 7.5

HCO_3, 22

His serum is negative for ketones. On physical examination, J.M. has poor skin turgor and dry mucous membranes, and is responsive only to deep pain. His BP is 90/60 mm Hg with a pulse of 96 beats/minute. He has rales at the left lower base of his lung, and a chest radiograph confirms pneumonia. Despite aggressive fluid replacement, J.M.'s BG remains consistently greater than 250 mg/dL and his A1C is 11%. J.M. presents with very high glucose concentrations, but has no history of diabetes mellitus. What special factors contribute to a late and atypical presentation of diabetes in the elderly?

Diabetes in the elderly commonly is underdiagnosed and undertreated because it often presents atypically.[278,279] Classic symptoms associated with diabetes mellitus may be masked by other illnesses, entirely absent, or explained away by the normal aging process. For example, polyuria is minimized by higher renal thresholds for glucose, or it may be confounded by urinary incontinence or "prostate problems." Thirst is commonly blunted in elderly persons, increasing their risk of dehydration and electrolyte imbalance. Hunger can be altered by medications or depression. Fatigue often is discounted as "part of getting old," and weight loss, although sometimes profound, may be so gradual that it goes unnoticed for months to years. (See Table 53-28 for a comparison of presenting symptoms for diabetes mellitus in elderly patients compared with younger patients.)

Table 53-28

Presentation of Diabetes Mellitus in Elderly Patients Compared with Younger Patients

Metabolic Abnormality	Symptoms in Young Patients	Symptoms in Elderly Patients
Serum osmolality	Polydipsia	Dehydration, confusion, delirium
Glucosuria	Polyuria	Incontinence
Catabolic state owing to insulin deficiency	Polyphagia	Weight loss, anorexia

HYPEROSMOLAR HYPERGLYCEMIC STATE

CASE 53-17, QUESTION 2: J.M. is diagnosed with hyperosmolar hyperglycemic state (HHS). Why are the elderly predisposed to this condition, and what signs and symptoms are consistent with this diagnosis?

HHS is a condition characterized by extremely elevated plasma glucose concentrations (>600 mg/mL) and high serum osmolality (>320 mOsm/L) without ketoacidosis. Because patients with Type 2 diabetes have some residual insulin production, they are usually protected against excessive lipolysis and ketone production. Patients with Type 2 diabetes may exhibit HHS in later stages of diabetes as loss of β-cells becomes advanced and residual insulin production continues to drop.[156] Measurements of serum ketones and blood pH differentiate this condition from DKA (see Case 53-10). The condition occurs when urinary fluid and electrolyte losses secondary to glucosuria are inadequately replaced by oral fluid intake.[156]

HHS primarily occurs in the elderly because several factors predispose this population to hypodipsia. These include an inability to recognize thirst,[280] an inability to ask for fluids (e.g., dementia, sedation, intubation), and an inability to get fluids on demand (e.g., physical disabilities or restraints). Infections or other acute illnesses (e.g., MI, GI bleeding, pancreatitis) that exacerbate diabetes can interact with the hyperosmolar diuresis and hypodipsia to produce severe dehydration and hyperglycemia. Drugs that increase plasma glucose concentrations (e.g., glucocorticoids), increase diuresis, or decrease mentation also can contribute to this unfortunate situation.

J.M. presents with several symptoms of HHS dehydration, including osmolality greater than 320 mOsm/L, plasma glucose greater than 600 mg/dL, pH > 7.3, elevated bicarbonate, decreased skin turgor, hypotension, and the absence of serum ketones. His pneumonia was probably the precipitating factor. Treatment involves rapid IV hydration. Fluid replacement is provided in the same manner as with DKA. See Case 53-10, Question 2, and Table 53-24 for details.[156] Insulin infusion is given simultaneously. The initiation and rate adjustments are the same as with DKA, except that the plasma glucose cut-off to reduce the insulin infusion rate is 300 mg/dL (not 200 mg/dL as with DKA; see Case 53-10, Question 3, and Table 53-24 for details). Rehydration and insulin administration corrected J.M's metabolic imbalance, allowing his diabetes control to be addressed.

GOALS OF THERAPY

CASE 53-17, QUESTION 3: What are the goals of therapy for J.M.?

It is widely recognized that strict glycemic control is associated with an increased incidence of hypoglycemia.[29] In the elderly patient with age-related autonomic dysfunction and CVD, hypoglycemia may present without the usual premonitory symptoms and can result in severe adverse effects such as angina, seizures, stroke, or MI. Therefore, the general tendency when treating elderly diabetic patients is to aim for slightly less aggressive glycemic goals. Thus, an FBG target of between 100 and 140 mg/dL with postprandial glucose values less than 180 mg/dL and an A1C goal of close to 8%, while avoiding hypoglycemia, is appropriate in this frail patient.[7]

DIET AND EXERCISE

CASE 53-17, QUESTION 4: How should diet and exercise recommendations be modified for elderly diabetic patients such as J.M.?

Nutrition

The ADA recommends individualized MNT for all patients with diabetes mellitus. The Dietary Approaches to Stop Hypertension (DASH) diet and Mediterranean diets have been shown to be effective for glycemic control and lowering CVD risk.[51–53]

Because most elderly patients have Type 2 diabetes, nutrition and exercise programs are the initial steps in therapy. Older people with diabetes, especially those in a long-term care facility, have a tendency to be underweight rather than overweight.[51–53] Therefore, caution should be used when considering a weight-loss diet because this could cause malnutrition or dehydration. For obese individuals, a modest weight loss of 5% to 10% may be indicated. However, an involuntary weight gain or loss of more than 10 lb or 10% of body weight in less than 6 months should be carefully assessed.[51–53]

Several factors can adversely affect proper nutrition in the elderly. They include an impaired ability to shop for and prepare food, limited finances, an age-related decline in taste perceptions, and coexisting illnesses. Ill-fitting dentures, difficulty in chewing and swallowing, and lack of companionship during meals also can contribute to malnutrition as well.

High-fiber diets may lower BG and improve plasma lipids. However, high-fiber diets in frail, elderly patients, particularly those who are bedridden, should be used cautiously because they can be constipating and result in fecal impaction. Ambulatory patients, on the other hand, generally benefit from increased dietary fiber. Because many elderly patients are malnourished, a daily multivitamin preparation containing the recommended daily allowance of each vitamin should be prescribed.[51–53]

Exercise

Exercise in the elderly provides all the benefits derived by younger individuals. It increases well-being and glucose stability, and may decrease a propensity to fall. Exercise also improves BP, the lipid profile, hypercoagulability, and bone density. Physical activity is necessary to minimize any lean body mass loss that can occur with caloric restriction. For patients with arthritis, aquatic exercise may be substituted. Before such an exercise program is initiated, careful evaluation is mandatory to avoid myocardial ischemia or the acceleration of retinopathy.

SELECTING AN ANTIDIABETIC AGENT IN THE ELDERLY

CASE 53-17, QUESTION 5: Why is it important to institute drug therapy to treat J.M.'s diabetes? What considerations should be made in selecting an initial treatment regimen?

As in all patients with diabetes mellitus, poor glycemic control increases the risk of long-term complications. Although it is tempting to minimize the importance of glycemic control because these complications take so long to develop, patients such as J.M. may have had unrecognized hyperglycemia for many years before clinical diagnosis. Thus, many have already begun to develop complications. Furthermore, as life expectancy increases, one can expect that these individuals will live long enough to experience morbidity related to diabetes if they are not treated. Therefore, pharmacologic treatment should be considered in J.M.

The general approach to treating an elderly patient with Type 2 diabetes is basically the same as described in Case 53-11, Questions 3, 7, and 8. The initial choice of an antidiabetic agent should be based on the severity of hyperglycemia. Other considerations include body weight, coexisting diseases, and cost of the agent. Patients with IFG (FPG >100, but <126 mg/dL) should be treated with diet and exercise tailored to their individual capabilities. For patients with Type 2 diabetes, acarbose, a short-acting insulin secretagogue (e.g., nateglinide or repaglinide), pioglitazone, and a DPP-4 inhibitor are all appropriate options. Sulfonylurea-induced hypoglycemia is a concern in these patients. However, if inability to adhere to the multiple daily regimen is problematic, a short-acting sulfonylurea is an appropriate alternative agent. In J.M.'s case, metformin should probably be used in caution because he has chronic obstructive pulmonary disease increasing the risk of hypoxia. Also, he is older than 80 years of age and requires an assessment of his GFR, which is likely diminished. The favorable effect metformin has on weight is irrelevant in J.M. Thus, although the efficacy of metformin is comparable to that of sulfonylureas, it is not the agent of first choice for elderly patients such as J.M.[281,282] Patients with an FPG greater than 300 mg/dL and no overt stress should be considered insulin deficient and started on insulin therapy.

HYPERTENSION

CASE 53-18

QUESTION 1: L.S. is a 53-year-old, obese man with an 8-year history of Type 2 diabetes. His current problems include a BP of 155/103 mm Hg (documented on two occasions), blurry vision, and impotence, which he now admits has troubled him for the last few years. Physical examination reveals decreased pedal pulses bilaterally, loss of sensation to monofilament testing, and evidence of an amputated toe on the right foot. His laboratory values are as follows:

FPG, 170 mg/dL
A1C, 7.8%
Total cholesterol, 240 mg/dL
Triglycerides, 160 mg/dL

L.S. has normal electrolyte values and albuminuria (180 mg/g creatinine). His only medication is metformin 500 mg PO BID. Describe the pathogenesis of hypertension in patients such as L.S. Why is it so important to treat his hypertension?

Seventy-five percent of adults with diabetes report having a BP of 130/80 mm Hg or more or use medications for hypertension.[1] Hypertension in Type 1 diabetes is usually of renal parenchymal

---

origin and occurs 1 to 2 years after the onset of nephropathy as indicated by albuminuria (see Case 53-19, Question 2).[7] The relationship between Type 2 diabetes and hypertension is more complex and not as closely correlated to nephropathy. In Type 2 diabetes, hypertension is often part of the metabolic syndrome and may be present for years before diabetes is actually detectable.

Patients with diabetes and hypertension have an increased risk for experiencing microvascular complications such as retinopathy and nephropathy. They are also at a twofold increased risk of having CVD.[7] A 5-mm Hg reduction in mean diastolic BP can produce a 37% reduction in microvascular complications, and a 10-mm Hg reduction in mean systolic BP had previously been found to reduce the risk of MI by 11% and death related to diabetes by 15%.[7,245,246] However, because lower BP targets are tested, the benefits are becoming less clear. In the ACCORD blood pressure study, the intensive control arm (achieved systolic BP of 119 mm Hg) did not reduce total cardiovascular events (nonfatal MI, nonfatal stroke or death from cardiovascular causes) compared with standard therapy (achieved systolic BP of <133 mm Hg).[9] However, microvascular benefits were observed, as was a statistically significant reduction in stroke. Therefore, the existing ADA BP goal of less than 140/90 mm Hg is reasonable, and lower goals should not be targeted in practice unless it can be done without adverse effects.[7]

Treatment includes weight management, exercise, sodium restriction (<1,500 mg/day), smoking cessation, and antihypertensive therapy. L.S. should be started on an angiotensin-converting enzyme inhibitor (ACEI). ACEI have traditionally been available as less expensive generics, although angiotensin receptor II blockers (ARB) are also available and appropriate. Many patients require two or three medications to achieve the target BP goal of less than 140/90 mm Hg.[7]

NEPHROPATHY

CASE 53-18, QUESTION 2: What is the significance of the presence of albumin in L.S.'s urine? How should it be managed?

Diabetes is the leading cause of end-stage renal disease and accounted for 44% of new cases of renal failure in 2005.[1,7] Diabetic nephropathy is characterized by nephrotic syndrome and azotemia. It is a major cause of death in patients with Type 1 diabetes and is an increasing source of morbidity in Type 2 diabetic individuals.[283] Thickening of the glomerular capillary basement membranes is the hallmark of diabetic nephropathy.[284] Diffuse deposition of basement membrane-like material expands the mesangium. This process narrows the capillary lumina, impedes blood flow, and thereby reduces the filtering surface area in the glomerulus. Hyperglycemia causes intraglomerular hypertension and renal hyperfiltration. Hyperfiltration is followed by albuminuria with minimal glomerulosclerosis, which still is potentially reversible. If left untreated, overt proteinuria occurs, and the patient usually progresses to nephrotic syndrome. Progression of diabetic renal disease can be accelerated in the presence of hypertension, proteinuria, and diabetic retinopathy. Lipid abnormalities also may contribute to the progression of glomerulosclerosis. Management includes early detection through screening for albuminuria, tight glucose control, use of ACEIs and ARBs for patients with albuminuria (to slow progression), aggressive management of hypertension that includes an ACEI or ARB as first-line therapy,[7] aggressive management of dyslipidemia, and smoking cessation. A thorough discussion on the management of diabetic nephropathy and end-stage renal disease is presented in Chapter 28, Chronic Kidney Diseases, and of hypertension in people with diabetes, in Chapter 9, Essential Hypertension.

Screening for and Confirmation of Albuminuria

The preferred method of screening for albuminuria is measurement of the albumin-to-creatinine ratio in a random spot collection (preferably the first-void or morning sample). Albuminuria is defined as a urinary albumin excretion of 30 mcg or more per milligram of creatinine (or mg albumin/g creatinine) during a spot collection.[7] Because of day-to-day variability in albumin excretion, two of three urine samples collected in a 3- to 6-month period need to be abnormal before a designation is made. Annual screening should be performed in patients with Type 1 diabetes with a duration of at least 5 years and in patients with Type 2 diabetes from the time of diagnosis. More frequent screening is indicated if hypertension, any increase in SCr, or retinopathy develops. Urine albumin concentrations can be falsely elevated over true baseline values by exercise within 24 hours, fever, infection, uncontrolled diabetes, uncontrolled hypertension, and HF.

On the basis of established criteria, L.S. has albuminuria (180 mg albumin/g creatinine). Management includes tight BG control and an ACEI or ARB should be started (L.S. should already be receiving one of these agents to treat his hypertension as noted). After initiation of therapy, continued periodic monitoring of the albuminuria is recommended to assess the response to therapy and progression of disease.[7] Serum potassium and creatinine levels should be followed as well.

CARDIOVASCULAR DISEASE

CASE 53-18, QUESTION 3: L.S. is treated with lisinopril 20 mg/day, which controls his BP and improves his albuminuria. His dose of metformin is titrated to 1,000 mg BID. Recent laboratory values include an FPG of 130 mg/dL, A1C of 6.0%, triglyceride level of 170 mg/dL, total cholesterol of 204 mg/dL, LDL-C of 135 mg/dL, and HDL-C of 35 mg/dL. How does the risk of heart disease for patients such as L.S. compare with that for persons without diabetes? What is the pathogenesis of CHD in persons with diabetes?

CHD is the leading cause of premature death in the Type 2 population and accounts for 50% of the deaths in people with diabetes. Relative to nondiabetic individuals, those with diabetes are 2 to 3 times more likely to develop CHD, and their risk of death after an MI also is 2 to 3 times higher than their nondiabetic counterparts. Women with diabetes, regardless of their age or menopausal status, have equal risk for CHD to that of nondiabetic men. These sobering figures point to the importance of minimizing or eliminating all other preventable risk factors for CVD in patients with diabetes (i.e., tobacco use, hypertension, hypercholesterolemia, obesity) through the prescription of exercise, diet, and appropriate medications.[285]

Pathogenesis

The pathogenesis of CVD in people with diabetes is complex. The metabolic syndrome with its attendant cardiovascular risk factors, dyslipidemia, inflammation, and hemostatic abnormalities are only some of the mechanisms under study.[19,286]

The most common lipid abnormality in Type 2 diabetes is hypertriglyceridemia (>150 mg/dL) with low levels of HDL-C (<40 mg/dL in men or <50 mg/dL in women), similar to the lipid profile seen in L.S. Poor control of Type 1 diabetes also is associated with low levels of HDL-C and a smaller, more-dense LDL particle. These lipid abnormalities, along with a greater prevalence of hypertension, contribute to the risk for CVD.

In patients with diabetes, clinical trials of lipid-lowering therapy (primarily with statins) have demonstrated primary and secondary CHD prevention. Although the evidence for the reduction in "hard" CVD outcomes (e.g., CHD death and nonfatal MI) is stronger in diabetic patients who have a high baseline CVD risk

---

(i.e., known CVD or very high LDL-C levels), the overall benefits of statins in patients with diabetes at moderate or high risk for CVD are convincing. Readers are referred to the ADA Standards of Medical Care for more detailed information on the CVD clinical trials in patients with diabetes.[7]

DYSLIPIDEMIA

CASE 53-18, QUESTION 4: Should L.S. be treated with drug therapy for his dyslipidemia?

The ACC/AHA made important changes in the management of dyslipidemia regarding cholesterol management recommendations. Although the previous ATP III guidelines focused on specific LDL and non-HDL cholesterol target goals, the new guidelines recommend initiating statin therapy based on cardiovascular risk. Cardiovascular risk is determined by age, comorbidities, lipid panel, social, and family history. The ACC/AHA guidelines recommend a moderate-intensity statin for diabetics between the ages of 40 to 75 with LDL between 70 and 189 mg/dL with estimated 10-year ASCVD (atherosclerotic cardiovascular disease) risk <7.5%. A high-intensity statin is recommended for diabetics between the ages of 40 to 75 with LDL between 70 and 189 mg/dL with estimated 10-year ASCVD risk > 7.5%. All patients between the ages of 40 to 75 are recommended a high-intensity statin if they have had a clinical ASCVD, including CHD, MI, unstable/stable angina, stroke, TIA, or peripheral arterial disease. Patients greater than the age of 75 are generally recommended to be initiated on a moderate-intensity statin due to risk of myalgias.[7]

Diet and exercise are cornerstones in the management of dyslipidemia in patients such as L.S. Weight loss is associated with improvements in insulin sensitivity and glucose control, as well as a reduction in triglycerides, total cholesterol, and LDL-C. Physical activity enhances weight loss and increases HDL-C levels. Thus, L.S.'s diet and exercise habits should be reassessed, and instruction in both should be reinforced as appropriate. Because insulin resistance may be the underlying cause of elevated lipids in these patients, efforts should be devoted to reversing insulin resistance as well. Given L.S.'s age and risk factors, a statin is indicated.

For a detailed discussion on statin therapy and other lipid-lowering agents see Chapter 8 (Dyslipidemias, Atherosclerosis, and Coronary Heart Disease chapter).

RETINOPATHY

CASE 53-18, QUESTION 5: L.S. is referred to the ophthalmologist for his persistent complaints of vision problems despite improvement in his glycemic control. He is diagnosed with mild background retinopathy. Should L.S. be concerned?

Ocular disorders related to diabetes are the leading cause of new cases of legal blindness in Americans. Patients with diabetes may experience blurred vision associated with poor glycemic control, but retinopathy, senile-type cataracts, and glaucoma are the complications that threaten sight. Diabetic retinopathy appears as early as 3 years after diagnosis and is evident in 90% of Type 1 diabetic individuals after 15 years. Comparable figures for patients with Type 2 diabetes treated with insulin and for those treated with diet and oral agents are 80% and 55%, respectively. Proliferative retinopathy is less prevalent, but nevertheless is present in 30% of people with Type 1 diabetes and in 10% to 15% of insulin-treated patients with Type 2 diabetes who have had diabetes for 15 years or longer.[287]

Patients with Type 1 diabetes should have a dilated retinal examination within 5 years of diagnosis; evaluation is not necessary before 10 years of age. Patients with Type 2 diabetes should have a comprehensive eye examination soon after diagnosis. The ADA recommends annual comprehensive eye examinations.[7] Less-frequent eye examinations (every 2–3 years) can be considered in patients with normal examinations based on the advice of an ophthalmologist.[287]

Current theories addressing the possible causes of this complication have been thoroughly reviewed.[287] Microvascular disease characterized by thickening of the capillary membrane may be the underlying lesion for two forms of retinopathy. The first and most common presentation is a nonproliferative retinopathy, which is characterized by microaneurysms that may progress to hard, yellow exudates, signifying chronic leakage, retinal edema, and punctate hemorrhage. This form of retinopathy may be associated with loss of central vision, but generally is associated with excellent visual prognosis. Focal laser photocoagulation of the retina in patients with nonproliferative diabetic retinopathy and macular edema decreases the likelihood of visual loss by 50%.[7]

A second, less common presentation is proliferative retinopathy. This form is characterized by neovascularization (presumably owing to retinal hypoxia). Neovascularization ultimately leads to fibrosis, vitreous hemorrhage, and retinal detachment. Photocoagulation therapy may arrest progression and decrease loss of vision associated with neovascularization.[287] Because hypertension, smoking, uremia, and hyperglycemia may lead to more rapid progression of the retinopathy, every effort should be made to eliminate these risk factors for L.S.

The ACCORD study assessed the impact of intensive glycemic, BP, and lipid control on the progression of retinopathy.[268] After 4 years, the rates of progression of diabetic retinopathy were reduced with intensive glycemic control (7.3% vs. 10.4% with standard therapy) and also with fenofibrate (6.5% vs. 10.2% with standard therapy of just a statin alone). Somewhat surprisingly, intensive BP control did not have an effect (10.4% vs. 8.8% with standard therapy). However, on closer interpretation, this finding makes sense as the BP in the standard therapy group achieved excellent control (133.5 mm Hg), so further lowering the BP (119.3 mm Hg in the intensive group) did not provide additional benefit in reducing the rate of retinopathy progression (see Case 53-19, Question 1).

CASE 53-18, QUESTION 6: Should L.S. be started on aspirin therapy?

The issue of aspirin use for primary prevention continues to be debated. The ADA recommends aspirin therapy as secondary prevention in patients with a history of CVD (e.g., MI, vascular bypass procedure, peripheral vascular disease, stroke or transient ischemic attack, claudication, or angina). Primary prevention is indicated in diabetic individuals who have a significant risk of CVD events (10-year risk >10%). Although the ADA lists several risk calculators that can be used in patients with diabetes, the UKPDS calculator can be downloaded and is relatively easy to use (**http://www.dtu.ox.ac.uk/riskengine/**).[288] In patients with a very low risk (10-year risk <5%), the ADA recommends against aspirin because the risk of significant bleeding outweighs the benefit for vascular event reduction.[288] Because risk calculation in patients with diabetes can be difficult, the ADA also provided more general clinical guidance and recommends that men older than the age of 50 and women older than the age of 60 who have at least one additional major risk factor (a family history of CVD, smoking, hypertension, albuminuria, dyslipidemia) are good candidates for aspirin therapy.[288] In elderly, patients assess the need for aspirin therapy. Clinicians should weigh risks versus benefits for the primary prevention of CVD events in patients >80 years of age. Newer studies have shown antiplatelet therapy renders this patient population to increased incidences of

---

bleeding without significant reduction in CVD events. L.S. has several cardiovascular risk factors (albuminuria, dyslipidemia, hypertension, obesity, and age) and should be started on aspirin therapy as primary prevention. L.S. should take an enteric-coated aspirin, 81 mg daily. Although some authors have suggested that higher doses of aspirin should be used because of the increased platelet reactivity that can be seen in people with diabetes, the clinical literature does not support this approach and the ADA does not recommend doses greater than 162 mg daily.[7,288]

AUTONOMIC NEUROPATHY: GASTROPARESIS

CASE 53-19

QUESTION 1: H.D. is a 36-year-old man with a 20-year history of Type 1 diabetes. He has poor glycemic control (A1C, 12%) and complains of frequent, severe hypoglycemic reactions that "don't make sense." According to H.D., "I have insulin reactions right after I eat, but later on, my glucose concentrations are sky high." H.D. presents to the diabetes clinic with a 2-month history of nausea, postprandial fullness, early satiety, and occasional vomiting, all of which are unrelieved by antacids. H.D. also has peripheral neuropathy involving both his hands and feet and manifestations of autonomic neuropathy (impotence and orthostatic hypotension). An upper GI series was ordered to rule out peptic ulcer disease and gastroesophageal reflux disease, and a solid-meal, gastric emptying study using scintigraphy indicates the diagnosis of diabetic gastroparesis. What is the cause of diabetic gastroparesis? How should H.D. be treated?

Autonomic neuropathy may present as gastroparesis with feelings of bloating and nausea, urinary retention, impotence in men (manifested as retrograde ejaculation or an inability to attain an erection), postural hypotension, tachycardia, and diarrhea with incontinence of stool.[289] The presence of autonomic insufficiency may have profound effects on the patient's response to vasodilating drugs and ability to counteract hypoglycemia.

Poor glycemic control with "unexplained" hypoglycemia may result from the disrupted delivery of food to the intestine; that is, glucose delivery does not correspond with prandial insulin action. As a result, the BG levels can fluctuate greatly. Many patients with diabetic gastroparesis, like H.D., have had diabetes for many years and also have evidence of peripheral and autonomic neuropathies.

Conventional antiemetic therapy is usually not helpful in the treatment of gastroparesis. Prokinetic agents, such as metoclopramide, are considered first-line therapy.[290] Metoclopramide increases gut motility through indirect cholinergic stimulation of the gut muscle. However, symptomatic improvement does not always correlate with improved gastric emptying, which implies that the effectiveness of metoclopramide also is related to its centrally mediated antiemetic activity. A usual starting dose of metoclopramide is 10 mg orally 4 times daily (QID), 30 minutes before meals and at bedtime. Although treatment may not eliminate all symptoms, it should minimize most of the patient's complaints. Patients should be monitored for tardive dyskinesia, a potentially irreversible and disfiguring condition that is characterized by involuntary movements of the tongue, face, or extremities. In 2009, the FDA added tardive dyskinesia as a black box warning for metoclopramide.[291]

The risk of tardive dyskinesia increases with the duration of treatment and the total cumulative dose.

Other pharmacotherapeutic interventions include domperidone (not available in the United States), cisapride (withdrawn from the US market), erythromycin, and cholinergic agonists.[290] A key component to treating H.D.'s gastroparesis is improving his glycemic control. Also, H.D. should be advised to try eating smaller, more frequent meals and to chew his food well; this of course will require adjustments to his prandial insulin therapy. Also, eating a low-fiber and low-fat diet may help with his symptoms.[290]

PERIPHERAL NEUROPATHY

CASE 53-19, QUESTION 2: Six months after institution of metoclopramide 10 mg QID and several insulin adjustments, H.D.'s GI symptoms have been alleviated, and his diabetes is now reasonably well controlled as evidenced by elimination of hypoglycemic episodes and a recent A1C of 7.5%. However, H.D. has been complaining of increasing bilateral foot pain, which he describes as a burning, tingling, or prickly sensation. An examination of his feet reveals cool extremities with absent pulses, reduced vibration perception, and loss of 10-g monofilament pressure sensation. What are appropriate steps that can be taken to alleviate H.D.'s peripheral neuropathy?
